#### Abstract

A first-principles approach for active chiral hard disks is presented, that explicitly accounts for steric interactions on the two-body level. We derive an effective one-body equation for the joint probability distribution of positions and angles of the particles. By projecting onto the angular modes, we write a hierarchy for the lowest hydrodynamic modes, i.e. particle density, polarisation, and nematic tensor. Introducing dimensionless variables in the equations, we highlight the assumptions, which - though inherent - are often included implicit in typical closure schemes of the hierarchy. By considering different regimes of the Péclet number, the wellknown models in active matter can be obtained through our consideration. Explicitly, we derive an effective diffusive description and by going to higher orders in the closure scheme, we show that this first-principles approach results in the recently introduced Active Model B +, a natural extension of the Model B for active processes. Remarkably, here we find that chirality can change the sign of the phenomenological activity parameters.

Keywords: first-principles approach, active chiral particles, steric interactions, hierarchy of angular modes, Active Model B+

## 1. Introduction

The analytic model of an Active Chiral Particle (ACP) [1-5] represents an extension to the well-known Active Brownian Particle (ABP) model [6-9] with additional active chirality. These models have proven very useful as they come as a first step in generalising equilibrium models to include non-equilibrium, active contributions for microscopic agents. They constitute a minimalist attempt to describe directed motion on the microscale and are found to lead to emerging complex structures on the macroscale. For that reason, they are widely used in the analytic description of non-equilibrium systems $10-12$.

The ABP model describes the overdamped motion of a tagged particle influenced by two contributions: firstly, equilibrium fluctuations of the surrounding medium, which give rise to the well-known equilibrium Langevin description. The particle is assumed to diffuse with a spatial diffusion coefficient $D_{T}$. Secondly, the particle experiences a non-equilibrium driving force, that might originate from an internal energy depot or external energy input $13 \sqrt{15}$. In the simplest case, this scenario is modelled as a self-propulsion with a (constant) velocity $v$ along an orientation vector $\hat{\mathbf{e}}(\theta)$. In the model of an ABP, the self-propulsion direction gets randomised by assuming that the orientation vector additionally is performing rotational diffusion on the unit-sphere with the diffusion coefficient $D_{R}$. Despite its simplicity, this "toy" ABP model has proven tremendously successful in analytical analysis and as a simulation model to describe active matter on a macroscale 16, 17. Emerging complex macroscopic phases such as motility-induced phase separations [18-23], (chemo-) tactic behaviour [24, 25], flocking [26, 27], or swarming [28 30] have been reported.

The ABP model has been further developed to include active processes that explicitly break the spatial symmetry via an effect of active chirality $\omega[1-4$. This generalisation in the model allows to describe even more complex emerging phenomena, such as odd viscosity [31, 32], finite-size rotating clusters [33, 34], hyperuniform behaviour [35, 36] and edge currents at interfaces [37-39]. This analytical extension is inspired by experimental observation of bacteria 40-42], sperm cells [43, 44], or syntactical particles [45, 46] as well as macroscopic chiral robots [47, 49], which show an archetypal chirality in their trajectories on the microscale. Remarkably, already over a century ago, experimental observations were made in living organisms, which showed that trajectories of certain microorganisms such as Loxodes and Paramecium break the spatial symmetry and need an interpretation in terms of chiral self-propulsion [50].

An alternative, more coarse-grained viewpoint for describing the emerging complex structures in active systems is based on continuum field-theoretical models of active matter. The starting point is to address the diffusive behaviour of a conserved order parameter, such as the mean particle probability-density function (PDF) $\varrho(\mathbf{x}, t)$, where $\varrho(\mathbf{x}, t) \mathrm{d} \mathbf{x}$ describes the probability of finding a particle in the interval $\mathbf{x}$ and $\mathbf{x}+\mathrm{d} \mathbf{x}$ at time $t$, as in the well-known Model B [51]. This model successfully describes the equilibrium behaviour of matter, and especially the dynamics of phase separation [52].

An inherent assumption in the derivation of these field-theoretical models is that the underlying processes follow the detailed-balance dynamics, that is broken in active systems. It is, therefore, natural that field theories that aim to describe the behaviour of active matter have to revisit the foundations and need to go beyond the detailedbalance restrictions. Successive works culminated in the recently introduced, so-called Active Model $B+(A M B+)$ 53 55, that attracted a lot of interest lately 56-59. Continuum approaches, very recently, have also been extended to include active chirality and specifically account for broken-time reversal symmetries [36, 60, 61].

The modelling of inter-particle interactions is crucial for such continuum approaches. While previous approaches are predominantly focused on interaction potentials, here we model the interactions via a geometric approach instead. The approach was originally introduced by Bruna and Chapman in Refs. 62, 63 and thereafter successfully applied to ABPs already [64]. The basic idea is to include particle interactions by restricting the domain of definition of the time-evolution equation and thereby creating forbidden areas, which correspond to situations with a particle overlap. We apply this idea to the ACP model and derive an effective one-body description of the full one-particle PDF $p(\mathbf{x}, \theta, t)$ to find a particle at position $\mathbf{x}$ with the selfpropulsion vector of angle $\theta$ at time $t$ after starting with the sharp initial conditions $\mathbf{x}=\mathbf{x}_{0}, \theta=\theta_{0}$, i.e. $p\left(\mathbf{x}, \theta, t_{0}\right)=\delta\left(\mathbf{x}-\mathbf{x}_{0}\right) \delta\left(\theta-\theta_{0}\right)$ at $t=t_{0}$. The resulting timeevolution equation explicitly accounts for two-particle steric interactions and therefore its validity is restricted to the dilute limit. To arrive at a field-theoretical description for the mean particle PDF $\varrho(\mathbf{x}, t)$, one typically proceeds by integrating out the effect of the angle [65, 66]. We follow this procedure and arrive at an (infinite) hierarchy of the hydrodynamic modes of the active particle, of which the mean particle PDF constitutes the zeroth order mode. This hierarchy is mathematically very similar to the famed Bogoliubov-Born-Green-Kirkwood-Yvon (BBGKY) hierarchy in kinetic theory [67]. Similar to that hierarchy, in continuous active matter theories one is also required to close the hierarchy to make analytic progress 68, 69].

We transform the closure problem into a perturbation problem and derive two field-theoretical descriptions for ACPs, based on the strictness of assumption on the perturbation parameters. This gives us access to the otherwise phenomenological coefficients in these models. We show that both an effective diffusive description and the AMB + can be obtained within our approach, depending on the order of the closure scheme. Our work moreover suggests that the AMB+ is a natural generalisation of equilibrium field theories to describe the continuum behaviour of active matter. We further have first-principles access to the coefficients in the AMB+ and it turns out, that, surprisingly, they are altered by active chirality in such a way that they can even change sign as a function of chirality.

The remainder of this work is organised as follows. In Section 2.1 we introduce the mathematical model and describe our approach to deal with inter-particle interactions in the geometric sense. In Section 2.2 we derive in detail the effective one-body timeevolution equation of the PDF. To our understanding, the physics community is rather
unaware of this specific method to handle inter-particle interactions, for which we introduce it in appropriate detail. In Section 2.3 we thereafter derive the hierarchy of hydrodynamic modes, and in Section 2.4 we introduce the mathematical steps to close the hierarchy. In Section 2.5 we go one step beyond the simplest closure and find that the time-evolution of the mean particle PDF equals the form predicted by the $\mathrm{AMB}+$. In Section 3 we conclude and provide an outlook to further and related works.

## 2. Theory: From active chiral particles to the Active Model B +

### 2.1. Model

In this Section, we introduce the model of interacting ACPs as sketched in Fig. 1a and how to deal with their excluded-volume interactions in a geometric sense, see also Fig. 1b. We finish by formulating an effective one-body description.
2.1.1. Setup. We consider the dynamics of $N$ interacting ACPs in two dimensions. The particles centres $\mathbf{x}_{i}(t)$ and angular coordinates $\theta_{i}(t), i \in\{1, \ldots, N\}$ move according to the overdamped Langevin dynamics [5, 70]

$$
\begin{align*}
\frac{\partial}{\partial t} \mathbf{x}_{i} & =v \hat{\mathbf{e}}\left(\theta_{i}\right)+\sqrt{2 D_{T}} \boldsymbol{\eta}_{i}(t)  \tag{1a}\\
\frac{\partial}{\partial t} \theta_{i} & =\omega+\sqrt{2 D_{R}} \zeta_{i}(t) \tag{1b}
\end{align*}
$$

Here $\boldsymbol{\eta}_{i}(t)$ and $\zeta_{i}(t)$ are independent Gaussian white noises with correlators $\left\langle\eta_{i, \alpha}(t) \eta_{j, \beta}\left(t^{\prime}\right)\right\rangle=\delta_{i j} \delta_{\alpha \beta} \delta\left(t-t^{\prime}\right)$ and $\left\langle\zeta_{i}(t) \zeta_{j}\left(t^{\prime}\right)\right\rangle=\delta_{i j} \delta\left(t-t^{\prime}\right)$, where Greek indices $\alpha, \beta$ refer to particle coordinates and Latin indices $i, j$ refer to particle labels. $v$ is the (constant) active self-propulsion velocity, $\omega$ the active torque and $\hat{\mathbf{e}}\left(\theta_{i}\right)=$ $\left(\cos \left(\theta_{i}\right), \sin \left(\theta_{i}\right)\right)^{\mathrm{T}}$ is the unit orientation vector, where $(\cdot)^{\mathrm{T}}$ denotes a matrix transpose. Note that for $\omega=0$, the model of Eqs. (1a) and (1b) reduces to the well-known model of ABPs. $D_{T}$ and $D_{R}$ are the translational and rotational diffusion coefficients, respectively. Note that the diffusion coefficients have different physical units, $\left[D_{T}\right]=$ $\mathrm{m}^{2} / \mathrm{s}$ and $\left[D_{R}\right]=1 / \mathrm{s}$.

The $N$ identical disk-like particles have a diameter $d$ and are assumed to interact hard-core with each other. For an illustration of the model system see also Fig. 1a, The ACPs are modelled to diffuse in a spatially bounded domain $\mathbf{x}_{i}(t) \in \Omega \subset \mathbb{R}^{2}$ of typical size $L \times L$ and their angular coordinates are $\theta_{i}(t) \in[0,2 \pi)$. Using dimensionless quantities by rescaling with $L$, the typical size of the domain is set to unity, whereas the diameter of the particle becomes $\varepsilon_{d}=d / L$. We restrict the analysis to a dilute system, i.e., we assume that $N \varepsilon_{d} \ll 1$. In contrast to typical approaches to model the interactions, that is, via an interaction-potential term in the spatial Langevin equation (1a), we instead restrict the domain of definition of the centre-ofmass coordinates $\mathbf{x}_{i}(t)$. We thereby follow a geometric approach to model particle interactions as established by Bruna and Chapman 62, 63] that already has proven successful in various contexts $71-73$. These authors also showed in a recent work 64
that within this model they can derive additional nonlinear cross-diffusion terms for the description of sterically interacting ABPs, compared to more classical treatments of interacting ABPs 74, 75.

The fundamental idea in modelling steric interactions in this geometric sense is that Eq. (1a) is defined on a restricted (spatial) domain $\Omega_{\varepsilon_{d}}^{N}=\left\{\left(\mathbf{x}_{1}, \ldots, \mathbf{x}_{N}\right) \in \Omega^{N} ; \forall i \neq\right.$ $\left.j:\left|\mathbf{x}_{i}(t)-\mathbf{x}_{j}(t)\right| \geq \varepsilon_{d}\right\}$ due to the excluded volume. The full model including Eq. (1b) therefore is defined on $\Lambda^{N}=\Omega_{\varepsilon_{d}}^{N} \times[0,2 \pi)^{N}$. Note that as the angular coordinate is not affected by the steric interactions, its domain of definition is not restricted. While for the angular coordinate we assume periodic boundary conditions, the cost of treating the particle interactions by restricting the domain of definition is that we have generated an inner (moving) boundary as apparent from Fig. 1a. At this boundary, particles perform hard elastic collisions similar to the container walls. Both inner and container-wall boundaries therefore are treated with reflective boundaries. To simplify this problem, we observe that for a dilute system finding configurations in the system where three particles are close, or two particles are close to a container wall is of the order $\mathcal{O}\left(\varepsilon_{d}^{2} N^{2}\right)$. Configurations where two particles are close or one particle is close to the wall, in contrast, are of the order $\mathcal{O}\left(\varepsilon_{d} N\right)[62,63]$. It is therefore reasonable to assume that in a dilute system, two-body collisions dominate the interactions and we can safely ignore higher-order correlations. As we assume that all particles are identical, it is sufficient to consider a system with $N=2$ particles. In the end we will scale the resulting interaction contribution by the particle number, which is justified as long as we stay within the dilute limit.
2.1.2. Joint Fokker-Planck equation. The Fokker-Planck equation (FPE) for the twobody joint $\operatorname{PDF} P_{2}(t)=P_{2}\left(\mathbf{x}_{1}, \theta_{1}, \mathbf{x}_{2}, \theta_{2}, t\right)$, defined on $\Lambda^{2}$, reads 76

$$
\begin{align*}
\frac{\partial}{\partial t} P_{2}(t)= & \nabla_{1} \cdot\left[D_{T} \nabla_{1}-v \hat{\mathbf{e}}\left(\theta_{1}\right)\right] P_{2}(t)+\frac{\partial}{\partial \theta_{1}}\left[D_{R} \frac{\partial}{\partial \theta_{1}}-\omega\right] P_{2}(t) \\
& +\nabla_{2} \cdot\left[D_{T} \nabla_{2}-v \hat{\mathbf{e}}\left(\theta_{2}\right)\right] P_{2}(t)+\frac{\partial}{\partial \theta_{2}}\left[D_{R} \frac{\partial}{\partial \theta_{2}}-\omega\right] P_{2}(t) \tag{2a}
\end{align*}
$$

Here $\nabla_{i}$ denotes the partial differential vector operator with respect to the position of particle $i \in\{1,2\}$. The reflective boundary condition reads

$$
\begin{equation*}
\mathbf{n}_{1} \cdot\left[D_{T} \nabla_{1}-v \hat{\mathbf{e}}\left(\theta_{1}\right)\right] P_{2}(t)+\mathbf{n}_{2} \cdot\left[D_{T} \nabla_{2}-v \hat{\mathbf{e}}\left(\theta_{2}\right)\right] P_{2}(t)=0 \tag{2b}
\end{equation*}
$$

valid on $\partial \Lambda^{2}=\partial \Omega_{\varepsilon_{d}}^{2}=\partial \Omega^{2} \cup \mathcal{S}_{\text {coll }}$, where $\mathcal{S}_{\text {coll }}=\left\{\left(\mathbf{x}_{1}, \mathbf{x}_{2}\right) \in \Omega^{2} ;\left|\mathbf{x}_{1}(t)-\mathbf{x}_{2}(t)\right|=\varepsilon_{d}\right\}$ is the so-called (inner) collision surface. For an illustration see Fig. 1b, $\mathbf{n}_{i}$ in Eq. (2b) is the outward unit normal vector of disk $i$. Note that $\mathbf{n}_{i}=\mathbf{0}$ for $\mathbf{x}_{j} \in \partial \Omega^{2}$ for $(i, j)=(1,2)$ and $(2,1)$ due to particle conservation, as well as $\mathbf{n}_{1}=-\mathbf{n}_{2}$ on $\mathcal{S}_{\text {coll }}$, due to elastic collisions of particles. For the angular coordinate Eq. (2a) is supplemented with the periodic boundary condition

$$
\begin{equation*}
P_{2}\left(\theta_{i}=0\right)=P_{2}\left(\theta_{i}=2 \pi\right) . \tag{2c}
\end{equation*}
$$

Figure 1: (a) Sketch of the model setup of the $i$ th spherical ACP of diameter $d$. The particle is self-propelled by the active speed $v$ whose direction rotates with the active frequency $\omega$. It is embedded in a thermal bath giving rise to fluctuations in the spatial and angular coordinates $\left(\mathbf{x}_{i}, \theta_{i}\right)$ with respective strengths $\propto \sqrt{D_{T}}$ and $\propto \sqrt{D_{R}}$, see Eqs. (1a) and (1b), respectively. (b) The particle coordinates are defined on $\Lambda^{2}=\Omega_{\varepsilon_{d}}^{2} \times[0,2 \pi)^{2}$, where $\Omega_{\varepsilon_{d}}^{2}=\left\{\left(\mathbf{x}_{1}, \mathbf{x}_{2}\right) \in \Omega^{2} ;\left|\mathbf{x}_{1}(t)-\mathbf{x}_{2}(t)\right| \geq \varepsilon_{d}\right\}$ is the allowed (rescaled) configuration space within the bounded domain $\Omega \subset \mathbb{R}^{2}$ and subtracted by the regions of a particle overlap (white area). This excluded-volume creates a reflecting boundary on $\partial \Lambda^{2}=\partial \Omega^{2} \cup \mathcal{S}_{\text {coll }}$, made up from the container walls $\partial \Omega^{2}$ and an inner moving, so-called collision surface $\mathcal{S}_{\text {coll }}=\left\{\left(\mathbf{x}_{1}, \mathbf{x}_{2}\right) \in \Omega^{2} ;\left|\mathbf{x}_{1}(t)-\mathbf{x}_{2}(t)\right|=\varepsilon_{d}\right\}$. Note that $\varepsilon_{d}=d / L$, where $L \times L=|\Omega|$ is the typical size of the bounded domain $\Omega$.

It is convenient to use the structural similarities of the spatial and angular coordinates and write Eq. (2a) in terms of joint variables $\chi_{i}=\left(\mathbf{x}_{i}, \theta_{i}\right)$. The diffusion coefficients form a diffusion matrix $\mathbf{D}=\operatorname{diag}\left(D_{T}, D_{T}, D_{R}\right)$ and the joint drift reads $\mathbf{f}\left(\theta_{i}\right)=\left(v \hat{\mathbf{e}}\left(\theta_{i}\right), \omega\right)^{\mathrm{T}}$. The FPE (2a) written in the joint variables becomes

$$
\begin{equation*}
\frac{\partial}{\partial t} P_{2}(t)=\nabla_{\chi_{1}} \cdot\left[\mathbf{D} \nabla_{\chi_{1}}-\mathbf{f}\left(\theta_{1}\right)\right] P_{2}(t)+\nabla_{\chi_{2}} \cdot\left[\mathbf{D} \nabla_{\chi_{2}}-\mathbf{f}\left(\theta_{2}\right)\right] P_{2}(t), \tag{3}
\end{equation*}
$$

valid on $\Lambda^{2}$. We here use the joint partial differential operator $\nabla_{\chi_{i}}=\left(\nabla_{i}, \partial / \partial \theta_{i}\right)^{T}$.
We are interested in analytically capturing the effects of particle collisions on the one-body diffusive behaviour. Therefore, we aim at deriving an effective description for the full one-body PDF $p\left(\mathbf{x}_{1}, \theta_{1}, t\right)=p\left(\chi_{1}, t\right)$, which is defined as

$$
\begin{equation*}
p\left(\chi_{1}, t\right)=\int_{\Lambda\left(\chi_{1}\right)} \mathrm{d} \chi_{2} P_{2}(t)=\int_{0}^{2 \pi} \mathrm{~d} \theta_{2} \int_{\Omega \backslash \mathrm{B}_{\varepsilon_{d}}\left(\mathbf{x}_{1}\right)} \mathrm{d} \mathbf{x}_{2} P_{2}(t) \tag{4}
\end{equation*}
$$

where we take particle one to be the test particle of interest. The area $\Lambda\left(\chi_{1}\right)$ of integration is given by all allowed configurations for the second particle to be placed everywhere apart from the excluded volume created by the first particle, i.e. $\Lambda\left(\chi_{1}\right)=\Omega \backslash \mathrm{B}_{\varepsilon_{d}}\left(\mathbf{x}_{1}\right) \times[0,2 \pi)$, where $\mathrm{B}_{\varepsilon_{d}}\left(\mathbf{x}_{1}\right)$ is the disk of radius $\varepsilon_{d}$ centred at $\mathbf{x}_{1}$.

### 2.2. Effective one-body description

In this Section, we perform the integration to arrive at an effective one-body description and encounter that the effect of particle collisions results in a so-called collision integral. We solve this integral by the method of matched asymptotic expansions and provide the effective one-body description. This Section follows Ref. [64] and adapts it to ACPs to review and introduce the geometric method to deal with particle interactions to the reader.
2.2.1. The collision integral. Integrating Eq. (2a) over the reduced configuration space $\Lambda\left(\chi_{1}\right)$ results in

$$
\begin{align*}
\frac{\partial}{\partial t} p\left(\chi_{1}, t\right)= & \int_{\Lambda\left(\chi_{1}\right)} \mathrm{d} \chi_{2} \nabla_{\chi_{1}} \cdot\left[\mathbf{D} \nabla_{\chi_{1}}-\mathbf{f}\left(\theta_{1}\right)\right] P_{2}(t) \\
& +\int_{\Lambda\left(\chi_{1}\right)} \mathrm{d} \chi_{2} \nabla_{\chi_{2}} \cdot\left[\mathbf{D} \nabla_{\chi_{2}}-\mathbf{f}\left(\theta_{2}\right)\right] P_{2}(t) \tag{5}
\end{align*}
$$

We can easily evaluate the second integral, in which integration and differentiation are with respect to the same variable. Using the divergence theorem and applying the boundary conditions of Eqs. (2b) and $22 c$, we find

$$
\begin{align*}
& \int_{\Lambda\left(\chi_{1}\right)} \mathrm{d} \chi_{2} \nabla_{\chi_{2}} \cdot\left[\mathbf{D} \nabla_{\chi_{2}}-\mathbf{f}\left(\theta_{2}\right)\right] P_{2}(t) \\
& =\int_{0}^{2 \pi} \mathrm{~d} \theta_{2} \int_{\partial \mathrm{B}_{\varepsilon_{d}}\left(\mathbf{x}_{1}\right)} \mathrm{dS}_{2} \mathbf{n}_{2} \cdot\left[D_{T} \nabla_{1}-v \hat{\mathbf{e}}\left(\theta_{1}\right)\right] P_{2}(t) \tag{6}
\end{align*}
$$

where $\mathrm{dS}_{2} \mathbf{n}_{2}$ is the outward surface element of $\mathbf{x}_{2}$ and we used that $\mathbf{n}_{1}=-\mathbf{n}_{2}$ on $\partial \mathrm{B}_{\varepsilon_{d}}\left(\mathbf{x}_{1}\right)$ and $\mathbf{n}_{1}=\mathbf{0}$ for $\mathbf{x}_{2} \in \partial \Omega$.

The first integral in Eq. (5) cannot be evaluated that simply since integration and differentiation are with respect to different particle labels. Instead, we have to use the Reynolds transport theorem extended to spatial variation of integrals [77,78]. Together with an additional use of the divergence theorem this results in

$$
\begin{align*}
& \int_{\Lambda\left(\chi_{1}\right)} \mathrm{d} \chi_{2} \nabla_{\chi_{1}} \cdot\left[\mathbf{D} \nabla_{\chi_{1}}-\mathbf{f}\left(\theta_{1}\right)\right] P_{2}(t)=\nabla_{\chi_{1}} \cdot\left[\mathbf{D} \nabla_{\chi_{1}}-\mathbf{f}\left(\theta_{1}\right)\right] p\left(\chi_{1}, t\right) \\
& \quad-\int_{0}^{2 \pi} \mathrm{~d} \theta_{2} \int_{\partial \mathrm{B}_{\varepsilon_{d}\left(\mathbf{x}_{1}\right)}} \mathrm{dS}_{2} \mathbf{n}_{2} \cdot\left[D_{T}\left(2 \nabla_{1}+\nabla_{2}\right)+v \hat{\mathbf{e}}\left(\theta_{1}\right)\right] P_{2}(t) \tag{7}
\end{align*}
$$

For details of this calculation, see Appendix A. We combine this integral with Eq. (6) and find the effective equation for the full one-body PDF $p\left(\chi_{1}, t\right)$ according to Eq. (5) as

$$
\begin{align*}
\frac{\partial}{\partial t} p\left(\chi_{1}, t\right)= & \nabla_{\chi_{1}} \cdot\left[\mathbf{D} \nabla_{\chi_{1}}-\mathbf{f}\left(\theta_{1}\right)\right] p\left(\chi_{1}, t\right) \\
& -D_{T} \int_{0}^{2 \pi} \mathrm{~d} \theta_{2} \int_{\partial \mathrm{B}_{\varepsilon_{d}}\left(\mathbf{x}_{1}\right)} \mathrm{dS}_{2} \mathbf{n}_{2} \cdot\left(\nabla_{1}+\nabla_{2}\right) P_{2}\left(\chi_{1}, \chi_{2}, t\right) \tag{8}
\end{align*}
$$

In analogy to kinetic theory $\sqrt[67]{ }$, we refer to this integral as the collision integral and denote it by $I\left(\chi_{1}, t\right)$. It captures the effect of two-body hard-disk collisions on

Figure 2: The description of the problem changes from a particle-focused to a fixedparticle perspective. The second particle is measured in relative units. Technically we change from a description of $\left(\mathbf{x}_{1}, \theta_{1}\right)$ for particle one and $\left(\mathbf{x}_{2}, \theta_{2}\right)$ for particle two in (a) to a description of $\left(\mathbf{x}_{1}, \theta_{1}\right)$ for the effectively fixed particle one and the relative coordinate $\left(\mathbf{x}_{1}+\varepsilon_{d} \mathbf{x}, \theta_{1}+\theta\right)$ for particle two in (b). One advantage of this coordinate change is that the collision surface in the new coordinates is given by the condition $|\mathbf{x}|=1$.
a probabilistic level. To evaluate this integral, we have to find an expression for the joint PDF $P_{2}\left(\chi_{1}, \chi_{2}, t\right)$ in terms of the one-body PDF $p\left(\chi_{1}, t\right)$, similar to the classical closure problem in kinetic theory, known as the BBGKY hierarchy. This relation will be specifically relevant in regions where the particles are close, and where evaluating the collision integral will contribute to the effective description.
2.2.2. Matched asymptotic expansion. We aim at an approximation for $P_{2}$ via the method of matched asymptotic expansion $[62,64,71,79]$. We can suppose that when the particles are far apart they are independent, given the hard-disk nature of the interaction. In this so-called outer region, we define the outer joint PDF as $P^{\text {out }}\left(\chi_{1}, \chi_{2}, t\right)=P_{2}\left(\chi_{1}, \chi_{2}, t\right)$ and due to the independency argument we find that

$$
\begin{equation*}
P^{\text {out }}\left(\chi_{1}, \chi_{2}, t\right)=p\left(\chi_{1}, t\right) p\left(\chi_{2}, t\right)+\varepsilon_{d} P_{(1)}^{\text {out }}\left(\chi_{1}, \chi_{2}, t\right)+\mathcal{O}\left(\varepsilon_{d}^{2}\right) . \tag{9}
\end{equation*}
$$

Note that $P_{(1)}^{\text {out }}$ is a function denoting the corrections at first order $\mathcal{O}\left(\varepsilon_{d}\right)$ to the independence argument [80].

In contrast, when the two particles are close, the particles are correlated due to interactions and we perform a variable change in this so-called inner region. We fix particle one and measure the distance to this particle with respect to $\varepsilon_{d}$, see Fig. 2. The coordinate change reads as $\left(\chi_{1}, \mathbf{x}_{2}, \theta_{2}\right) \mapsto\left(\chi_{1}, \mathbf{x}_{1}+\varepsilon_{d} \mathbf{x}, \theta_{1}+\theta\right)$. The inner PDF is
defined as $P^{\text {in }}\left(\chi_{1}, \mathbf{x}, \theta, t\right)=P_{2}\left(\chi_{1}, \chi_{2}, t\right)$. Rewriting the two-particle problem into inner coordinates, we find

$$
\begin{align*}
\varepsilon_{d}^{2} \frac{\partial}{\partial t} P^{\mathrm{in}}= & 2 D_{T} \nabla_{\mathbf{x}}^{2} P^{\mathrm{in}}+\varepsilon_{d} \nabla_{\mathbf{x}} \cdot\left[v\left(\hat{\mathbf{e}}\left(\theta_{1}\right)-\hat{\mathbf{e}}\left(\theta_{1}+\theta\right)\right)-2 D_{T} \nabla_{\mathbf{x}_{1}}\right] P^{\mathrm{in}} \\
& +\varepsilon_{d}^{2} \nabla_{\mathbf{x}} \cdot\left[D_{T} \nabla_{\mathbf{x}}-v \hat{\mathbf{e}}\left(\theta_{1}\right)\right] P^{\mathrm{in}} \\
& +\varepsilon_{d}^{2}\left[D_{R}\left(\frac{\partial}{\partial \theta_{1}}-\frac{\partial}{\partial \theta}\right)^{2}-\omega \frac{\partial}{\partial \theta_{1}}\right] P^{\mathrm{in}} . \tag{10a}
\end{align*}
$$

The no-flux boundary condition then translates into inner coordinates as

$$
\begin{equation*}
2 D_{T} \mathbf{x} \cdot \nabla_{\mathbf{x}} P^{\mathrm{in}}=\varepsilon_{d} \mathbf{x} \cdot\left[D_{T} \nabla_{\mathbf{x}_{1}}-v\left(\hat{\mathbf{e}}\left(\theta_{1}\right)-\hat{\mathbf{e}}\left(\theta_{1}+\theta\right)\right)\right] P^{\mathrm{in}} \tag{10b}
\end{equation*}
$$

which is valid on the collision surface $\mathcal{S}_{\text {coll }}$ defined in inner coordinates by $\left\{\mathbf{x} \in \mathbb{R}^{2} ;|\mathbf{x}|=\right.$ $1\}$. When formulating the problem in inner coordinates, we have an additional boundary condition, which is replacing the otherwise implicit natural boundary condition on $P_{2}$, i.e., $\lim _{\left|\mathbf{x}_{i}\right| \rightarrow \infty} P_{2}=0, i \in\{1,2\}$. In the framework of the matched asymptotic expansion, this condition implies that the inner PDF has to match the outer PDF as $|\mathbf{x}| \rightarrow \infty$. An expansion of the outer solution in inner coordinates gives

$$
\begin{equation*}
P^{\text {out }}\left(\chi_{1}, \chi_{2}, t\right)=p p^{+}+\varepsilon_{d}\left(p \mathbf{x} \cdot \nabla_{\mathbf{x}_{1}} p^{+}+P_{(1)}^{\text {out },+}\right)+\mathcal{O}\left(\varepsilon_{d}^{2}\right), \tag{10c}
\end{equation*}
$$

where we have introduced the shorthand notations $p=p\left(\chi_{1}, t\right), p^{+}=p\left(\mathbf{x}_{1}, \theta_{1}+\theta, t\right)$ and $P_{(1)}^{\text {out, }+}=P_{(1)}^{\text {out }}\left(\chi_{1}, \mathbf{x}_{1}, \theta_{1}+\theta, t\right)$. Expanding the inner solution in powers of $\varepsilon_{d}$, $P^{\text {in }}=P_{(0)}^{\text {in }}+\varepsilon_{d} P_{(1)}^{\text {in }}+\mathcal{O}\left(\varepsilon_{d}^{2}\right)$, the zeroth-order inner problem becomes

$$
\begin{array}{ll}
0=2 D_{T} \nabla_{\mathbf{x}}^{2} P_{(0)}^{\mathrm{in}}, & \\
0=2 D_{T} \mathbf{x} \cdot \nabla_{\mathbf{x}} P_{(0)}^{\mathrm{in}}, & \text { on }|\mathbf{x}|=1, \\
P_{(0)}^{\mathrm{in}} \sim p p^{+}, & \text {as }|\mathbf{x}| \rightarrow \infty, \tag{11c}
\end{array}
$$

with the straight-forward solution

$$
\begin{equation*}
P_{(0)}^{\mathrm{in}}=p p^{+} . \tag{12}
\end{equation*}
$$

Note here, that $P_{(0)}^{\mathrm{in}}$ is no function of the separation coordinate $\mathbf{x}$.
Before we can write the first-order inner problem, we note from Eq. $10 a$, that at order $\mathcal{O}\left(\varepsilon_{d}\right)$, we have that

$$
\begin{align*}
0 & =2 D_{T} \nabla_{\mathbf{x}}^{2} P_{(1)}^{\mathrm{in}}+\varepsilon_{d} \nabla_{\mathbf{x}} \cdot\left[v\left(\hat{\mathbf{e}}\left(\theta_{1}\right)-\hat{\mathbf{e}}\left(\theta_{1}+\theta\right)\right)-2 D_{T} \nabla_{\mathbf{x}_{1}}\right] P_{(0)}^{\mathrm{in}} \\
& =2 D_{T} \nabla_{\mathbf{x}}^{2} P_{(1)}^{\mathrm{in}}, \tag{13}
\end{align*}
$$

as $P_{(0)}^{\mathrm{in}}$ is no function of the separation variable $\mathbf{x}$. Taking this into account, the firstorder inner problem reads

$$
\begin{array}{ll}
0=2 D_{T} \nabla_{\mathbf{x}}^{2} P_{(1)}^{\mathrm{in}}, & \\
\mathbf{x} \cdot \nabla_{\mathbf{x}} P_{(1)}^{\mathrm{in}}=\mathbf{x} \cdot \mathbf{A}\left(\chi_{1}, \theta, t\right), & \text { on }|\mathbf{x}|=1 \\
P_{(1)}^{\mathrm{in}} \sim \mathbf{x} \cdot \mathbf{B}\left(\chi_{1}, \theta, t\right)+P_{(1)}^{\text {out, }+}, & \text { as }|\mathbf{x}| \rightarrow \infty \tag{14c}
\end{array}
$$

where

$$
\begin{align*}
& \mathbf{A}\left(\chi_{1}, \theta, t\right)=\frac{1}{2 D_{T}}\left(D_{T} \nabla_{\mathbf{x}_{1}}\left(p p^{+}\right)-v\left(\hat{\mathbf{e}}\left(\theta_{1}\right)-\hat{\mathbf{e}}\left(\theta_{1}+\theta\right)\right) p p^{+}\right),  \tag{15}\\
& \mathbf{B}\left(\chi_{1}, \theta, t\right)=p \nabla_{\mathbf{x}_{1}} p^{+} . \tag{16}
\end{align*}
$$

The solution can be obtained straightforwardly and is given by $62,63,73,77$

$$
\begin{equation*}
P_{(1)}^{\mathrm{in}}=a+P_{(1)}^{\mathrm{out},+}+\mathbf{x} \cdot \mathbf{B}-\frac{\mathbf{x}}{|\mathbf{x}|^{2}} \cdot(\mathbf{A}-\mathbf{B}), \tag{17}
\end{equation*}
$$

where $a$ is an arbitrary integration constant. According to the expansion ansatz $P^{\mathrm{in}} \sim P_{(0)}^{\mathrm{in}}+\varepsilon_{d} P_{(1)}^{\mathrm{in}}+\mathcal{O}\left(\varepsilon_{d}^{2}\right)$ for the inner PDF, we thus found that

$$
\begin{align*}
P^{\mathrm{in}}= & p p^{+}+\varepsilon_{d} \mathbf{x} \cdot p \nabla_{\mathbf{x}_{1}} p^{+}-\varepsilon_{d} \frac{\mathbf{x}}{2|\mathbf{x}|^{2}} \cdot\left[p^{+} \nabla_{\mathbf{x}_{1}} p-p \nabla_{\mathbf{x}_{1}} p^{+}\right. \\
& \left.-\frac{v}{D_{T}}\left(\hat{\mathbf{e}}\left(\theta_{1}\right)-\hat{\mathbf{e}}\left(\theta_{1}+\theta\right)\right) p p^{+}\right]+\varepsilon_{d}\left(a+P_{(1)}^{\text {out },+}\right)+\mathcal{O}\left(\varepsilon_{d}^{2}\right) . \tag{18}
\end{align*}
$$

2.2.3. Evaluation of the collision integral. We now use this approximate inner solution to evaluate the collision integral. In inner coordinates, this is given by

$$
\begin{equation*}
I\left(\chi_{1}, t\right)=\varepsilon_{d} D_{T} \int_{0}^{2 \pi} \mathrm{~d} \theta \int_{|\mathbf{x}|=1} \mathrm{dS}_{\mathbf{x}} \mathbf{x} \cdot \nabla_{\mathbf{x}_{1}} P^{\mathrm{in}}\left(\chi_{1}, \mathbf{x}, \theta, t\right) \tag{19}
\end{equation*}
$$

where we used that $\mathbf{n}_{\mathbf{x}}=-\mathbf{x}$ on the collision surface $\mathcal{S}_{\text {coll }}$. Using the inner solution of Eq. (18), the collision integral becomes

$$
\begin{align*}
I\left(\chi_{1}, t\right)= & \varepsilon_{d} D_{T} \int_{0}^{2 \pi} \mathrm{~d} \theta\left[\nabla_{\mathbf{x}_{1}}\left(p p^{+}\right)\right]_{\alpha} \int_{|\mathbf{x}|=1} \mathrm{dS} \mathbf{x}_{\mathbf{x}} x_{\alpha}  \tag{20}\\
& +\varepsilon_{d}^{2} D_{T} \int_{0}^{2 \pi} \mathrm{~d} \theta\left[\nabla_{\mathbf{x}_{1}} P_{(1)}^{\text {out, }+}\right]_{\alpha} \int_{|\mathbf{x}|=1} \mathrm{dS}_{\mathbf{x}} x_{\alpha} \\
& +\varepsilon_{d}^{2} D_{T} \int_{0}^{2 \pi} \mathrm{~d} \theta\left[\nabla_{\mathbf{x}_{1}}\left(p \nabla_{\mathbf{x}_{1}} p^{+}\right)_{\alpha}\right]_{\beta} \int_{|\mathbf{x}|=1} \mathrm{dS}_{\mathbf{x}} x_{\alpha} x_{\beta} \\
& -\varepsilon_{d}^{2} \frac{D_{T}}{2} \int_{0}^{2 \pi} \mathrm{~d} \theta\left[\nabla_{\mathbf{x}_{1}}\left(p^{+} \nabla_{\mathbf{x}_{1}} p-p p \nabla_{\mathbf{x}_{1}} p^{+}\right)_{\alpha}\right]_{\beta} \int_{|\mathbf{x}|=1} \mathrm{~d} S_{\mathbf{x}} \frac{x_{\alpha} x_{\beta}}{|\mathbf{x}|^{2}} \\
& -\varepsilon_{d}^{2} \frac{v}{2} \int_{0}^{2 \pi} \mathrm{~d} \theta\left[\hat{\mathbf{e}}\left(\theta_{1}\right)-\hat{\mathbf{e}}\left(\theta_{1}+\theta\right)\right]_{\alpha}\left[\nabla_{\mathbf{x}_{1}}\left(p p^{+}\right)\right]_{\beta} \int_{|\mathbf{x}|=1} \mathrm{~d} S_{\mathbf{x}} \frac{x_{\alpha} x_{\beta}}{|\mathbf{x}|^{2}}
\end{align*}
$$

where we introduced the Einstein convention, i.e., that the sum over double indices is implicit: $x_{\alpha} x_{\alpha}=\sum_{\alpha=1}^{2} x_{\alpha} x_{\alpha}$. There are two types of integrals appearing in Eq. (20), namely, an integral of an outer unit normal vector over the whole unit sphere: $\int_{|\mathbf{x}|=1} \mathrm{dS}_{\mathbf{x}} x_{\alpha}=0$, by geometrical insight; and

$$
\begin{equation*}
\int_{|\mathbf{x}|=1} \mathrm{dS}_{\mathbf{x}} \frac{x_{\alpha} x_{\beta}}{|\mathbf{x}|^{2}}=\int_{|\mathbf{x}|=1} \mathrm{dS}_{\mathbf{x}} x_{\alpha} x_{\beta}=\pi \delta_{\alpha \beta} \tag{21}
\end{equation*}
$$

valid in two dimensions.

As $\theta_{1}$ is independent of $\theta$ and kept constant for the variation of $\theta$, we can define a new variable $\tilde{\theta}=\theta_{1}+\theta$ and use it to integrate out the $\theta$-dependence in Eq. 20). Therefore, we define the mean particle PDF

$$
\begin{equation*}
\varrho(\mathbf{x}, t)=\int_{0}^{2 \pi} \mathrm{~d} \tilde{\theta} p(\mathbf{x}, \tilde{\theta}, t) \tag{22}
\end{equation*}
$$

and the polarisation

$$
\begin{equation*}
\boldsymbol{\sigma}(\mathbf{x}, t)=2 \int_{0}^{2 \pi} \mathrm{~d} \tilde{\theta} p(\mathbf{x}, \tilde{\theta}, t) \hat{\mathbf{e}}(\tilde{\theta}) \tag{23}
\end{equation*}
$$

as the zeroth and first-order moment of the full one-body PDF, respectively. Note the factor of 2 in the definition of the polarisation, which is necessary for consistency later on. Thus, the collision integral becomes

$$
\begin{equation*}
I\left(\chi_{1}, t\right)=\varepsilon_{d}^{2} \frac{\pi}{2} \nabla_{\mathbf{x}_{1}} \cdot\left[3 D_{T} p \nabla_{\mathbf{x}_{1} \varrho}-D_{T} \varrho \nabla_{\mathbf{x}_{1}} p+v\left(\hat{\mathbf{e}}\left(\theta_{1}\right) \varrho-\frac{\boldsymbol{\sigma}}{2}\right) p\right] \tag{24}
\end{equation*}
$$

where $\varrho=\varrho\left(\mathbf{x}_{1}, t\right), \boldsymbol{\sigma}=\boldsymbol{\sigma}\left(\mathbf{x}_{1}, t\right)$, and, as a reminder, $p=p\left(\mathbf{x}_{1}, \theta_{1}, t\right)$.
As expected, the dependence on the separation coordinates $\mathbf{x}$ and $\theta$ vanished, since we integrated out the effect of the second particle on the first. Thus, we can back-transform into the original variables and then drop the index in the notation $\left(\mathbf{x}_{1}, \theta_{1}\right) \mapsto(\mathbf{x}, \theta)$, similarly for the operator $\nabla_{1} \mapsto \nabla$. We insert the evaluated collision integral into Eq. (8) and find the effective time-evolution equation for the full one-body PDF $p$. This equation is valid for two hard-interacting particles. As introduced in the beginning, in the dilute system of $N$ particles, we can safely assume that two-particle collisions dominate any higher-order correlations. The tagged particle can have ( $N-1$ ) inner regions with each of the remaining particles under this assumption. It is thus sufficient to multiply the collision integral by the factor of $(N-1)$ to account for the interaction effect in the effective, dilute one-body description.
2.2.4. Effective one-body equation. We introduce the dimensionless parameter $\phi=$ $\varepsilon_{d}^{2} \pi(N-1) / 4$, which for large $N$ approximately equals the area fraction of the particles. We then write the obtained time-evolution equation for the full one-body PDF $p=$ $p(\mathbf{x}, \theta, t)$ as

$$
\begin{align*}
\frac{\partial}{\partial t} p= & -v \nabla \cdot[(1-2 \phi \varrho) \hat{\mathbf{e}}+\phi \boldsymbol{\sigma}] p+\frac{\partial}{\partial \theta}\left[D_{R} \frac{\partial}{\partial \theta}-\omega\right] p \\
& +D_{T} \nabla \cdot[(1-2 \phi \varrho) \nabla p+6 \phi p \nabla \varrho] \tag{25}
\end{align*}
$$

valid in the dilute limit, i.e., $\phi \ll 1$. Without the effect of chirality $(\omega=0)$ this equation was recently derived in Ref. 64 for ABPs. This systematic derivation of the one-body description results in additional cross-diffusion terms ( $\propto \varrho \nabla p, \propto p \nabla \varrho)$. These terms were not reported in literature on phenomenological approaches [74, 75], works relying on approximations of the pair correlation function [57,81, or classical dynamical density functional theory [82, 83]. These cross-diffusion, however, become specifically important when dealing with different particle labels, and thus accounting for particle-identity in
the effective description [62, 73. Further, recent work shows that for ABPs, Eq. (25) forms a well-posed problem for which a stationary state exists 84].

In the context of phase-separating active matter, typically effective self-propulsion velocities $v(\varrho)$ are introduced [18, 85 and constitute an essential theoretical trick to achieve phase separation in purely repulsive active systems 65]. To the lowest order in density, they are typically of the form of $v(\varrho)=v_{0}(1-a \phi \varrho)\left(v_{0}=\right.$ const) which was also derived using linear response theory [86. The reason is simple: in regions with many particles, the effective swim speed must be reduced. It is interesting that we naturally obtain this form in the geometric integration procedure for hard interactions, and we can constitute that $a=2$ for steric interactions.

### 2.3. Hierarchy of hydrodynamic equations

We now project the time-evolution equation for the full one-body $\operatorname{PDF} p(\mathbf{x}, \theta, t)$ on its angular modes, where the zeroth-order mode is given by the mean particle PDF $\varrho(\mathbf{x}, t)$. This procedure generates a hierarchy of coupled particle differential equations for the time evolution of the modes. We analyse these equations to provide a footing to systematically close the hierarchy in the next Section.
2.3.1. Expansion in harmonic modes. To overcome the angular dependence of the full one-body PDF, we expand the full one-body PDF in eigenfunctions of the rotation operator $\partial^{2} / \partial \theta^{2}$ in Eq. (25). This results in a Fourier expansion, in which modes of order $n \in \mathbb{N}_{0}$ have eigenvalue $-n^{2}$ in two dimensions. This expansion can be brought into the form

$$
p(\mathbf{x}, \theta, t)=\frac{1}{2 \pi}(\varrho(\mathbf{x}, t)+\boldsymbol{\sigma}(\mathbf{x}, t) \cdot \hat{\mathbf{e}}(\theta)+\mathbf{Q}(\mathbf{x}, t): \hat{\mathbf{e}}(\theta) \otimes \hat{\mathbf{e}}(\theta)+\Upsilon(\theta))(26)
$$

where $\mathbf{Q}: \hat{\mathbf{e}} \otimes \hat{\mathbf{e}}=Q_{\alpha \beta} \hat{e}_{\beta} \hat{e}_{\alpha}$ denotes the full contraction with the outer product $\hat{\mathbf{e}} \otimes \hat{\mathbf{e}}$, and $\Upsilon(\theta)$ refers to higher order modes. Notably, higher order (outer) products of the selfpropulsion vector $\hat{\mathbf{e}}(\theta)=(\cos (\theta), \sin (\theta))^{\mathrm{T}}$ naturally appear as modes in this expansion. Therefore, the expansion is also known as a Cartesian multipole expansion [87] and finds wide use in the theory of liquid crystals [88]. Note that there exists an equivalent approach, as other works in active matter use an angular multipole expansion at this stage [25, 65, 89], where the second mode is replaced by $(\hat{\mathbf{e}}(\theta) \otimes \hat{\mathbf{e}}(\theta)-\mathbf{1} / 2)$, where $\mathbf{1}$ denotes the identity tensor. The two expansions are equivalent, as $\mathbf{Q}$ is a traceless object, see below.

The coefficients of the expansion are given by the mean particle PDF $\varrho(\mathbf{x}, t)$ (zerothorder mode), as defined above in Eq. (22), the mean polarisation $\boldsymbol{\sigma}(\mathbf{x}, t)$ (first-order mode), as defined above in Eq. (23), and the mean nematic order tensor (second-order mode)

$$
\begin{equation*}
\mathbf{Q}(\mathbf{x}, t)=4 \int_{0}^{2 \pi} \mathrm{~d} \theta p(\mathbf{x}, \theta, t) \quad\left(\hat{\mathbf{e}}(\theta) \otimes \hat{\mathbf{e}}(\theta)-\frac{\mathbf{1}}{2}\right) \tag{27}
\end{equation*}
$$

Note that due to the similarity with hydrodynamic theories, the coefficients are sometimes referred to as hydrodynamic coefficients, the hierarchy created by them as a hydrodynamic hierarchy 65, 69.

The inner product on the unit-sphere is defined in the standard way as

$$
\begin{equation*}
\langle f(\theta), g(\theta)\rangle=\int_{0}^{2 \pi} \mathrm{~d} \theta f(\theta) g(\theta) \tag{28}
\end{equation*}
$$

for two functions $f$ and $g$. The modes of the Cartesian multipole expansion, $\left\{\hat{\mathbf{e}}^{n} ; n \in\right.$ $\left.\mathbb{N}_{0}\right\}$, form an orthogonal basis with respect to this scalar product. Therefore, we can project the full one-body PDF $p(\mathbf{x}, \theta, t)$ onto the modes and obtain the hydrodynamic coefficients

$$
\begin{align*}
& \langle p(\mathbf{x}, \theta, t), 1\rangle=\varrho(\mathbf{x}, t),  \tag{29a}\\
& \langle p(\mathbf{x}, \theta, t), \hat{\mathbf{e}}(\theta)\rangle=\frac{1}{2} \boldsymbol{\sigma}(\mathbf{x}, t),  \tag{29b}\\
& \langle p(\mathbf{x}, \theta, t), \hat{\mathbf{e}}(\theta) \otimes \hat{\mathbf{e}}(\theta)\rangle=\frac{1}{4} \mathbf{Q}(\mathbf{x}, t) . \tag{29c}
\end{align*}
$$

2.3.2. Time-evolution of modes. Using the orthogonality of modes, we can project the time-evolution equation for the full one-body PDF, Eq. 25), on each mode to obtain a time-evolution equation for the corresponding hydrodynamic coefficient. Projecting Eq. (25) on the zeroth-order mode, we obtain a time-evolution equation of the mean particle $\operatorname{PDF} \varrho$, which is given by

$$
\begin{equation*}
\frac{\partial}{\partial t} \varrho(\mathbf{x}, t)=D_{T} \nabla_{\alpha}\left[(1+4 \phi \varrho(\mathbf{x}, t)) \nabla_{\alpha} \varrho(\mathbf{x}, t)\right]-\frac{v}{2} \nabla_{\alpha} \sigma_{\alpha}(\mathbf{x}, t) . \tag{30}
\end{equation*}
$$

The mean particle PDF therefore obeys a continuity equation. This is expected on physical grounds as $\varrho$ is a conserved quantity. Specifically, this implies that $\varrho$ is a slow variable, i.e., a density perturbation of scale $\lambda$ relaxes on a time scale which diverges as $\lambda \rightarrow \infty$. This observation will be confronted with the time-evolution equation for the higher modes below. We further observe that the equation for the mean particle PDF needs an explicit input from the polarisation $\boldsymbol{\sigma}$. This coupling is induced by the activity $v$ in the model and persist for all modes, which generates a hierarchy. Formally this hierarchy is similar to the famed BBGKY hierarchy of kinetic theory [67], where also higher order modes implicitly alter the time-evolution of the mode in focus.

Projecting Eq. (25) onto the first order mode, we obtain a time-evolution equation for the mean polarisation $\boldsymbol{\sigma}$, which is given in component-form by

$$
\begin{align*}
& \frac{\partial}{\partial t} \sigma_{\alpha}(\mathbf{x}, t)=D_{T} \nabla_{\beta}\left[(1-2 \phi \varrho(\mathbf{x}, t)) \nabla_{\beta} \sigma_{\alpha}(\mathbf{x}, t)+6 \phi \sigma_{\beta}(\mathbf{x}, t) \nabla_{\alpha} \varrho(\mathbf{x}, t)\right] \\
& \quad-v \nabla_{\beta}\left[(1-2 \phi \varrho(\mathbf{x}, t))\left(\frac{Q_{\beta \alpha}(\mathbf{x}, t)}{2}+\varrho(\mathbf{x}, t) \delta_{\beta \alpha}\right)+\phi \sigma_{\beta}(\mathbf{x}, t) \sigma_{\alpha}(\mathbf{x}, t)\right] \\
& \quad-D_{R} \Gamma_{\alpha \beta} \sigma_{\beta}(\mathbf{x}, t) \tag{31}
\end{align*}
$$

Again, we observe that the time-evolution equation for the mean polarisation needs both input from the mean particle density $\varrho$ as well as from the nematic order tensor $\mathbf{Q}$. We further observe that in contrast to the time evolution of the mean particle density the
structure of this equation is different. While $\varrho$ obeys a continuity equation, Eq. (31) has a sink term: $-D_{R} \Gamma_{\alpha \beta} \sigma_{\beta}(\mathbf{x}, t)$. The polarisation, and as we will see, all higher modes therefore are not conserved quantities, and their dynamics are governed by the associated time scale of the sink term. For the mean polarisation, this time scale is given by $\tau_{1}=1 / D_{R} 90,91$.

This fundamental structural difference of the time-evolution equations arises in the $\theta$-term of the parental equation (25) of the hierarchy. While for the polarisation we find that $\hat{\mathbf{e}}$ is the $n=1$ st-order eigenfunction of the rotation operator with eigenvalue $-n^{2}=-1$, for the zeroth-order mode $\varrho$, the eigenvalue is zero. For the chirality-induced term of Eq. (25), we observe a similar phenomenon. In the projection procedure, we find that

$$
\begin{align*}
\left\langle\hat{e}_{\alpha}, \omega \frac{\partial}{\partial \theta} p\right\rangle & =\frac{\omega}{2 \pi} \int_{0}^{2 \pi} \mathrm{~d} \theta \hat{e}_{\alpha}(\theta) \frac{\partial}{\partial \theta} p(\mathbf{x}, \theta, t)  \tag{32a}\\
& =\left.\frac{\omega}{2 \pi} \hat{e}_{\alpha} p(\mathbf{x}, \theta, t)\right|_{0} ^{2 \pi}-\frac{\omega}{2 \pi} \int_{0}^{2 \pi} \mathrm{~d} \theta p(\mathbf{x}, \theta, t) \frac{\partial}{\partial \theta} \hat{e}_{\alpha}(\theta)  \tag{32b}\\
& =\varepsilon_{\alpha \beta} \frac{\omega}{2 \pi} \int_{0}^{2 \pi} \mathrm{~d} \theta p(\mathbf{x}, \theta, t) \hat{e}_{\beta}(\theta)  \tag{32c}\\
& =\frac{\omega}{2} \varepsilon_{\alpha \beta} \sigma_{\beta}(\mathbf{x}, t) \tag{32d}
\end{align*}
$$

where we used that $\partial / \partial \theta \hat{e}_{\alpha}(\theta)=-\varepsilon_{\alpha \beta} \hat{e}_{\beta}(\theta)$ and $\boldsymbol{\varepsilon}$ is the Levi-Civita symbol in two dimensions, defined by $\varepsilon_{x x}=\varepsilon_{y y}=0$ and $\varepsilon_{x y}=-\varepsilon_{y x}=1$. The boundary term in $(32 b)$ vanishes due to periodicity. When we are dealing with the zeroth-order mode, in contrast, the projection $\left\langle 1, \omega \frac{\partial}{\partial \theta} p\right\rangle$, reduces to the boundary term and therefore is zero due to periodicity in $\theta$.

The joint effect of the rotation operator and the active chirality is the origin of the sink term $-D_{R} \Gamma_{\alpha \beta} \sigma_{\beta}(\mathbf{x}, t)$, where $\boldsymbol{\Gamma}=(\mathbf{1}+\kappa \varepsilon)$ and $\kappa=\omega / D_{R}$ is the associated dimensionless parameter accounting for the effect of chirality. In a more general context, this parameter $\kappa$ is also referred to as the oddness parameter 60, 92 94, since under a reversal of the direction of chirality, $\omega \rightarrow-\omega, \kappa$ changes sign and therefore switches the off-diagonal elements of the tensor $\boldsymbol{\Gamma} \rightarrow \boldsymbol{\Gamma}^{\mathrm{T}}$.

We find the time-evolution equation for the nematic order tensor from projecting Eq. (25) on the second order mode $\hat{\mathbf{e}} \otimes \hat{\mathbf{e}}$

$$
\begin{align*}
\frac{\partial}{\partial t} Q_{\alpha \beta}(\mathbf{x}, t)= & \left.D_{T} \nabla_{\gamma}\left[(1-2 \phi \varrho(\mathbf{x}, t)) \nabla_{\gamma} Q_{\alpha \beta}(\mathbf{x}, t)+6 \phi Q_{\alpha \beta}(\mathbf{x}, t) \nabla_{\gamma} \varrho(\mathbf{x}, t)\right)\right] \\
& -v \nabla_{\gamma}\left[(1-2 \phi \varrho(\mathbf{x}, t)) A_{\alpha \beta \gamma \delta} \sigma_{\delta}(\mathbf{x}, t)+\phi \sigma_{\gamma}(\mathbf{x}, t) Q_{\alpha \beta}(\mathbf{x}, t)+\mathcal{O}(\Upsilon)\right] \\
& -4 D_{R} \tilde{\Gamma}_{\alpha \gamma} Q_{\gamma \beta}(\mathbf{x}, t) . \tag{33}
\end{align*}
$$

Here $A_{\alpha \beta \gamma \varepsilon}=\left(\delta_{\alpha \gamma} \delta_{\beta \varepsilon}+\delta_{\alpha \varepsilon} \delta_{\beta \gamma}-\delta_{\alpha \beta} \delta_{\gamma \varepsilon}\right) / 2$ and $\tilde{\boldsymbol{\Gamma}}=(\mathbf{1}+\kappa \boldsymbol{\varepsilon} / 2)$ again accounts for the chirality. The structural similarities of this equation to the polarisation equation are that (i) Eq. (33) couples to neighbouring modes in the hierarchy and to the zeroth order mode $\varrho$ and (ii) the relaxation dynamics of the nematic tensor is governed by the time scale $\tau_{2}=1 /\left(4 D_{R}\right)$ induced by the sink term of Eq. (33). Again we find that $\mathbf{Q}$, as
all higher-order modes, is not conserved. We observe that the relaxation time scale originates in the eigenvalues of the rotation operator, i.e., the relaxation time scale of the $n$th mode is given by $\tau_{n}=\tau / n^{2}=1 /\left(n^{2} D_{R}\right)$, where we denote $\tau=\tau_{1}=1 / D_{R}$ as the fundamental time scale and $n \geq 1$.

In principle, the time-evolution equations for all higher-order modes can be found by the same projection procedure as presented before. This results in an infinite system of coupled time-evolution equations. To get an analytical, meaningful result from this hierarchy, we have to close this hierarchy based on physical arguments about negligible contributions from higher-order modes.

### 2.4. Closure of the hierarchy

We proceed to introduce the physical arguments to close the hierarchy by neglecting higher-order modes. Therefore, this problem naturally amounts to a perturbative analysis of the hierarchy. As the result of the minimal non-trivial closure scheme, we find an effective diffusion equation for the mean particle density.
2.4.1. Adiabatic approximation. It would be a formidable task to find a general solution for the $n$th order hierarchical equation and plug this into the $(n-1)$ th order equation. By such a procedure, one aims to identify quasi-irrelevant modes for the effect on the time evolution of $\varrho$. But to our best knowledge, such a procedure has never been successfully applied before for a general order. Instead, it is convenient [5, 25, 57, 66, 69, 95, 97] to take advantage of the time scale separation in the system. The dynamics of the polarisation and all higher-order modes are governed by their respective time scale $\tau=\tau_{1}=1 / D_{R}$ induced by rotational diffusion. $\tau$ then reasonably can be assumed to be much smaller than the relaxation time scale of the density, which can be arbitrarily large. Therefore, formally we will investigate the limit of $\tau \rightarrow 0$, called adiabatic or quasi-stationarity approximation, since we adiabatically enslave the behaviour of higher order modes to the mean particle density and assume an instantaneous response to changes.

In some approaches, the adiabatic approximation is also handled differently. Especially in the context of phase separations, the nematic order tensor is assumed to be an adiabatic variable, but the polarisation is treated as a dynamical variable. This appears in active Brownian systems [69, 98, 99], but also in active chiral systems [95,100]. As explicitly shown there, such an ansatz can qualitatively improve the agreement of the analytical prediction with the numerical data, but it can rarely be treated fully analytically when aiming for the effect of higher-order modes on the relaxation of the mean particle PDF. In related hierarchy-closure problems, nevertheless, an analytic treatment of more than one dynamical variable and a shift of the adiabatic assumption to second order has recently been applied successfully in the framework of dynamical density functional theory [101,102]. Here many-body correlation functions form an analogous hierarchical problem, but the approach is analytically rather involved and it is not obvious how it can be applied to our situation. We, therefore, restrict our analysis
to the basic situation and assume all higher-order modes to be adiabatic.
We will demonstrate the adiabatic approximation for the polarisation equation, but the same arguments hold true for all higher-order modes. Pointing out the essentials, Eq. (31) can be written as

$$
\begin{equation*}
\frac{\partial}{\partial t} \sigma_{\alpha}+\frac{1}{\tau} \Gamma_{\alpha \beta} \sigma_{\beta}=f_{\alpha}(\varrho, \boldsymbol{\sigma}, \mathbf{Q}), \tag{34}
\end{equation*}
$$

where $\mathbf{f}$ denotes the leftover gradient-structure terms of Eq. (31). We can solve this equation formally by

$$
\begin{equation*}
\sigma_{\alpha}(\mathbf{x}, t)=\mathrm{e}^{-\Gamma_{\alpha \beta} t / \tau} \sigma_{\beta}(\mathbf{x}, 0)+\int_{0}^{t} \mathrm{~d} t^{\prime} \mathrm{e}^{-\Gamma_{\alpha \beta}\left|t-t^{\prime}\right| / \tau} f_{\beta}(\varrho, \boldsymbol{\sigma}, \mathbf{Q}), \tag{35}
\end{equation*}
$$

where $\varrho, \boldsymbol{\sigma}$ and $\mathbf{Q}$ have to be evaluated at $t^{\prime}$ inside the integral. The integrating factor $\mathrm{e}^{-\Gamma_{\alpha \beta} t / \tau}$ is defined as the usual matrix-exponential and can be reformulated as

$$
\begin{equation*}
\mathrm{e}^{-\Gamma_{\alpha \beta} t / \tau}=\mathrm{e}^{-t / \tau}\left(\cos \left(\kappa \frac{t}{\tau}\right) \delta_{\alpha \beta}-\sin \left(\kappa \frac{t}{\tau}\right) \varepsilon_{\alpha \beta}\right), \tag{36}
\end{equation*}
$$

using the anti-symmetry property of $\boldsymbol{\Gamma}$. The active chirality $(\kappa \propto \omega)$ therefore results in oscillations, which decay exponentially on the typical time scale $\tau$. The exponential factor further allows us to write $\int_{0}^{\infty} \mathrm{d} t \exp \left(-\Gamma_{\alpha \beta} t / \tau\right)=\tau \Gamma_{\alpha \beta}^{-1}$, which together with $\lim _{\tau \rightarrow 0} \exp \left(-\Gamma_{\alpha \beta}|t| / \tau\right)=0_{\alpha \beta}$ for $|t|>0$ results in $\lim _{\tau \rightarrow 0} \Gamma_{\alpha \gamma} \exp \left(-\Gamma_{\gamma \beta}|t| / \tau\right)=$ $2 \tau \delta_{\alpha \beta} \delta(t)$. Here the factor 2 originates from the integrals taken to be for positive times only. The formal solution of Eq. (35) evaluated in the limit of $\tau \rightarrow 0$ thus reads

$$
\begin{equation*}
\lim _{\tau \rightarrow 0} \sigma_{\alpha}(\mathbf{x}, t)=\tau \Gamma_{\alpha \beta}^{-1} f_{\beta}(\varrho, \boldsymbol{\sigma}, \mathbf{Q}), \tag{37}
\end{equation*}
$$

where now $\varrho, \boldsymbol{\sigma}$ and $\mathbf{Q}$ are functions of $t$. The corresponding adiabatic approximation for the nematic order tensor similarly reads

$$
\begin{equation*}
\lim _{\tau \rightarrow 0} Q_{\alpha \beta}(\mathbf{x}, t)=4 \tau \tilde{\Gamma}_{\alpha \gamma}^{-1} g_{\gamma \beta}(\varrho, \boldsymbol{\sigma}, \mathbf{Q}, \Upsilon) \tag{38}
\end{equation*}
$$

where $\mathbf{g}$ accounts for the leftover terms of Eq. (33) and the modes again are evaluated at $t$.
2.4.2. Closure of the hierarchy via perturbation approach. The adiabatic approximation as such does not suffice to close the hierarchy. The coupling to higher order modes in the hierarchy for each mode enters via the activity-induced term $-v \nabla$. $[(1-2 \phi \varrho) \hat{\mathbf{e}} p+2 \phi \boldsymbol{\sigma} p]$ from the parental equation (25). This coupling already takes place in interaction-free considerations $(\phi=0)$, as it specifically arises due to the appearance of the self-propulsion vector and first-order mode $\hat{\mathbf{e}}$. To effectively close the hierarchy we therefore have to argue that higher-order modes can be neglected as compared to lower ones. This consequently turns the closure of the hierarchy into a perturbation problem.

We introduce a dimensionless time via the natural time scale of the system $\tau$ and dimensionless space via the mean-particle distance $l_{\text {dist }}=L \sqrt{\phi}$. The two natural physical length scales in the system are the persistence length $l_{\text {pers }}=v / D_{R}$ induced by
activity and the diffusion length scale $l_{\text {diff }}=\sqrt{D_{T} / D_{R}}$ induced by thermal equilibrium fluctuations [64]. We denote the parameters, which arise when comparing the physical length scales with the dimensionless length scale $l_{\text {dist }}$ as $\varepsilon_{p}$ and $\varepsilon_{D}$ and observe the following relation between them:

$$
\begin{equation*}
\varepsilon_{p}=\frac{l_{\mathrm{pers}}}{l_{\mathrm{dist}}}, \quad \varepsilon_{D}=\frac{l_{\mathrm{diff}}}{l_{\mathrm{dist}}}, \quad \text { and } \quad \frac{\varepsilon_{p}}{\varepsilon_{D}}=\frac{l_{\mathrm{pers}}}{l_{\mathrm{diff}}}=\frac{v}{\sqrt{D_{T} D_{R}}}=\mathrm{Pe} \tag{39}
\end{equation*}
$$

Here Pe stands for the Péclet number, which measures the relation of activity-induced self-propulsion versus thermally induced displacement.

Here we take $\varepsilon_{p}$ and $\varepsilon_{D}$ to be two independent perturbation parameters. We show that depending on their relation to the Péclet number, different field theoretic descriptions can be obtained. The adiabatic assumption thereby justifies independent small active and passive length scales, since both $l_{\text {pers }} \propto \tau$ and $l_{\text {diff }} \propto \tau$. This treatment is in contrast to previous work, where this subtle point of taking both parameters small and not only their ratio (the Péclet number) was often left implicit or was overlooked.
$\varepsilon_{p}$ and $\varepsilon_{D}$ compare the active and passive physical length scales in the system to the dimensionless length scale, which we choose as the mean particle-particle distance. This is a careful choice, since the other natural length scales in the system, the particle diameter $d$ (which also equals the interaction length scale for hard systems) and the typical box size $L$ were too small and too big, respectively, and already form the small parameter $\phi \propto(d / L)^{2}$. Together with the assumption of a dilute system, the mean particle-particle distance appears as the correct length scale interpolating between a too-narrow or too-coarse-grained view on the dynamics.

The aforementioned analysis reveals that the coupling to higher-order modes takes place in the activity-induced term at each order. To close the hierarchy, we therefore need to decide up to which order we consider the parameter $\varepsilon_{p}$. For this work, and referring to what is typical in the literature [25, 57, 66, 69, 95, 97], we truncate the hierarchy at order $\mathcal{O}\left(\varepsilon_{p}^{3}\right)$. We thus ignore contributions from higher modes such as $\Upsilon$ in the nematic equation. Together with the adiabatic assumption Eq. (33) for the nematic tensor thus becomes

$$
\begin{align*}
Q_{\alpha \beta}(\mathbf{x}, t)= & \frac{\varepsilon_{D}}{4} \tilde{\Gamma}_{\alpha \delta}^{-1} \nabla_{\gamma}\left[(1-2 \phi \varrho(\mathbf{x}, t)) \nabla_{\gamma} Q_{\delta \beta}(\mathbf{x}, t)\right. \\
& \left.\left.+6 \phi Q_{\delta \beta}(\mathbf{x}, t) \nabla_{\gamma} \varrho(\mathbf{x}, t)\right)\right] . \tag{40}
\end{align*}
$$

Eq. (40) constitutes a fixed-point problem for Q. We observe that Eq. (40) has no sink term and therefore has a definite, perturbation-free solution given by $\mathbf{Q}=\mathbf{0}$. This is a generic observation: closing the hierarchy at order $\mathcal{O}\left(\varepsilon_{p}^{n}\right)$ results in the fixed-point problem for the $(n-1)$ th order mode to only have the trivial solution.
2.4.3. Effective diffusion equation. In the following, we investigate the resulting timeevolution equations for the density for different orders of truncation in the polarisation equation. We start with the first non-trivial case by allowing for terms of order $\mathcal{O}\left(\varepsilon_{p}^{1}\right)$
for the polarisation. Here, the adiabatic polarisation reads

$$
\begin{equation*}
\sigma_{\alpha}=-\varepsilon_{p} \Gamma_{\alpha \beta}^{-1}\left[(1-4 \phi \varrho) \nabla_{\beta \varrho} \varrho\right] . \tag{41}
\end{equation*}
$$

Note that since the diffusive parameter $\varepsilon_{D}$ originates from a Laplace operator it only appears at even powers. Thus, there is no term at order $\mathcal{O}\left(\varepsilon_{p} \varepsilon_{D}\right)$ that could be included at this closure of the polarisation. The mean particle density from Eq. (30) at this order becomes

$$
\begin{align*}
\frac{\partial}{\partial t} \varrho(\mathbf{x}, t)= & \varepsilon_{D}^{2} \nabla_{\alpha}\left[(1+4 \phi \varrho(\mathbf{x}, t)) \nabla_{\alpha} \varrho(\mathbf{x}, t)\right] \\
& +\frac{\varepsilon_{p}^{2}}{2} \frac{1}{1+\kappa^{2}} \nabla_{\alpha}\left[(1-4 \phi \varrho(\mathbf{x}, t)) \nabla_{\alpha} \varrho(\mathbf{x}, t)\right] . \tag{42}
\end{align*}
$$

As apparent, the chosen closure scheme results in a time-evolution equation of the mean particle density at order $\mathcal{O}\left(\varepsilon_{p}^{2}\right)$ and $\mathcal{O}\left(\varepsilon_{D}^{2}\right)$. Now, by comparing the terms under consideration with the truncated terms we can learn about the regime of validity of Eq. (42). This gives us that $(i) \varepsilon_{p}^{2} \gg \varepsilon_{p}^{3}$, which is consistent with our perturbative assumption of $\varepsilon_{p} \ll 1$, but we also find that $(i i) \varepsilon_{D}^{2} \gg \varepsilon_{p}^{3}$, which tells us that Eq. 42) is valid in the regime of $\mathrm{Pe} \ll 1 / \varepsilon_{p}^{1 / 2}$. Together $(i)$ and $(i i)$ do not form a precise upper bound to the Péclet number, in fact it can be arbitrarily large and therefore an analysis of the microscopic parameters is essential when using this field-theoretical description.

Eq. (42) is written in dimensionless form. Thus we can reintroduce the units of space and time, i.e., $\tau$ for time and $l_{\text {dist }}$ for space, compare also relation (39). The time-evolution equation for the mean density becomes

$$
\begin{equation*}
\frac{\partial}{\partial t} \varrho(\mathbf{x}, t)=\nabla \cdot\left[\left(D_{T}^{\mathrm{eff}}(\varrho)+D_{A}^{\mathrm{eff}}(\varrho)\right) \nabla \varrho(\mathbf{x}, t)\right] . \tag{43}
\end{equation*}
$$

The time evolution of $\varrho$ at this order thus follows an effective diffusion equation 65 , 74, 103, where $D_{T}^{\text {eff }}+D_{A}^{\text {eff }}$ form the interaction-corrected diffusion coefficients due to thermal and active motion, respectively, and are given by

$$
\begin{align*}
& D_{T}^{\mathrm{eff}}(\varrho)=D_{T}(1+4 \phi \varrho(\mathbf{x}, t)),  \tag{44a}\\
& D_{A}^{\mathrm{eff}}(\varrho)=D_{A}^{\omega}(1-4 \phi \varrho(\mathbf{x}, t)) . \tag{44b}
\end{align*}
$$

Here $D_{T}$ stands for the thermal (equilibrium) diffusion coefficient, as introduced in the microscopic Langevin description (1a). $D_{A}^{\omega}=D_{A}^{0} /\left(1+\kappa^{2}\right)=v^{2} /\left(2 D_{R}\left(1+\kappa^{2}\right)\right)$ is the chirality-affected active diffusion coefficient, which describes the ballistic motion. $D_{A}^{0}$ is thereby a characteristic of a purely active particle and relates it to the randomisation of the self-propulsion vector due to rotational diffusion. In accordance with observations in the literature 103106 , active chirality $\omega$ rescales the active diffusion $D_{A}^{0}$, as $D_{A}^{\omega}$ can also be written as $D_{A}^{\omega}=v^{2} D_{R} /\left(2\left(\omega^{2}+D_{R}^{2}\right)\right)$. Remember that $\kappa=\omega / D_{R}$.

Relations (44a) and (44b) state that hard-core interactions on the one hand enhance the thermal diffusion and on the other hand reduce the active diffusion. For the passive motion, this is in accordance with the observation that the collective diffusion, in what sense $D_{T}^{\text {eff }}(\varrho)$ also can be interpreted, gets enhanced by steric interactions 73, 77, 107. For the active motion similarly the interaction-reduction of the associated diffusion
coefficient $D_{A}^{\text {eff }}$ is no surprise. It rather can be regarded as an analytic necessity for the strong theory-, simulation-, and experiment-supported existence of motility-induced phase separations [19, 20, 108 110], i.e., the phenomenon that purely repulsive active systems can phase-separate as a function of particle density. This phenomenon is only possible if the associated diffusion process becomes unstable, i.e., the effective diffusion coefficient can formally turn negative.

### 2.5. Active Model $B+$

In this Section, we go one step beyond the simplest non-trivial closure approximation by considering mixed terms of the perturbation parameters. This amounts to a much richer field-theoretical description but for the price of a much narrower regime of validity. We find that the dynamics of the mean particle PDF follow the recently introduced AMB+, to which we, therefore have first-principles access for the parameters. Surprisingly here we find that the characteristic AMB+ parameters all change sign as a function of chirality.
2.5.1. Effect of mixed perturbation parameters. In this work, we treat both the activity as well as the thermal diffusion-induced length scales as small compared to the interparticle distance. This is justified by the assumption of a dilute system. We are thus formally dealing with a two-parameter perturbation theory. It is therefore natural that besides arguing for the smallness of each of the parameters $\varepsilon_{D} \ll 1$ and $\varepsilon_{p} \ll 1$, we also have to specify their relative size. This is only possible by making a third assumption about the Péclet number, the natural scale relating the active and passive motion of a tracer.

We already observed from Eq. (41) that the diffusion length-scale parameter $\varepsilon_{D}$ only appears in even powers (due to its origin in the second order Laplace operator). Therefore, we can go a step further in the truncation scheme, by considering the polarisation up to order $\mathcal{O}\left(\varepsilon_{p}^{1} \varepsilon_{D}^{2}\right)$. The adiabatic polarisation can self-consistently be obtained from Eq. (31) at the desired order to be

$$
\begin{align*}
\sigma_{\alpha}= & -\varepsilon_{p} \Gamma_{\alpha \beta}^{-1}\left[(1-4 \phi \varrho) \nabla_{\beta \varrho} \varrho\right] \\
& -\varepsilon_{p} \varepsilon_{D}^{2}\left(\Gamma^{-1}\right)_{\alpha \beta}^{2}\left[\nabla_{\gamma}^{2}-2 \phi\left(3 \varrho \nabla_{\gamma}^{2}-\left(\nabla_{\gamma}^{2} \varrho\right)+2\left(\nabla_{\gamma} \varrho\right) \nabla_{\gamma}\right)\right] \nabla_{\beta} \varrho . \tag{45}
\end{align*}
$$

We observe here that the higher-order gradient terms of the mean particle density arise together with a matrix product of the chiral matrix $\boldsymbol{\Gamma}$. For an arbitrary vector $\mathbf{a}$, the contraction of the relevant matrices contributes

$$
\begin{align*}
& a_{\alpha} \Gamma_{\alpha \beta}^{-1} a_{\beta}=\frac{1}{1+\kappa^{2}} a_{\alpha} a_{\alpha}  \tag{46a}\\
& a_{\alpha}\left(\Gamma^{-1}\right)_{\alpha \beta}^{2} a_{\beta}=\frac{1-\kappa^{2}}{\left(1+\kappa^{2}\right)^{2}} a_{\alpha} a_{\alpha} \tag{46b}
\end{align*}
$$

where due to the antisymmetric structure of $\Gamma^{-1}=(1-\kappa \varepsilon) /\left(1+\kappa^{2}\right)$ only the respective diagonal elements are relevant in the full contraction.

Inserting this expression for the polarisation into Eq. (30) for the time-evolution of the mean particle density $\varrho$, we obtain

$$
\begin{align*}
& \frac{\partial}{\partial t} \varrho(\mathbf{x}, t)=\varepsilon_{D}^{2} \nabla_{\alpha}\left[(1+4 \phi \varrho) \nabla_{\alpha} \varrho\right]+\frac{\varepsilon_{p}^{2}}{2} \frac{1}{1+\kappa^{2}} \nabla_{\alpha}\left[(1-4 \phi \varrho) \nabla_{\alpha} \varrho\right] \\
& \quad+\frac{\varepsilon_{p}^{2} \varepsilon_{D}^{2}}{2} \frac{1-\kappa^{2}}{\left(1+\kappa^{2}\right)^{2}} \nabla_{\alpha}\left[\nabla_{\gamma}^{2}-2 \phi\left(3 \varrho \nabla_{\gamma}^{2}-\left(\nabla_{\gamma}^{2} \varrho\right)+2\left(\nabla_{\gamma} \varrho\right) \nabla_{\gamma}\right)\right] \nabla_{\alpha} \varrho \tag{47}
\end{align*}
$$

It is now obvious that, to obtain this field-theoretical description for the density compared to Eq. (42), we further encounter the mixed term of order $\mathcal{O}\left(\varepsilon_{p}^{2} \varepsilon_{D}^{2}\right)$, which is only possible if this term is assumed to be much greater then the disregarded terme, e.g. that of order $\mathcal{O}\left(\varepsilon_{p}^{3}\right)$. An easy algebraic analysis shows that this is only possible when $\mathrm{Pe} \ll \varepsilon_{D} \ll 1$ due to the perturbative closure scheme.
2.5.2. Active Model $B+$. If we reintroduce physical units for space and time, i.e., $\tau$ for the time $l_{\text {dist }}$ for the space, compare also relation (39), we can arrange Eq. (47) in the form

$$
\begin{align*}
\frac{\partial}{\partial t} \varrho(\mathbf{x}, t)= & a \nabla^{2} \varrho+b \nabla^{2}\left(\varrho^{2}\right)-k_{0} \nabla^{4} \varrho-k_{1}\left[\nabla^{2}(\nabla \varrho)^{2}+2 \nabla^{2}\left(\varrho \nabla^{2} \varrho\right)\right] \\
& +\lambda \nabla^{2}(\nabla \varrho)^{2}-\xi \nabla \cdot(\nabla \varrho)\left(\nabla^{2} \varrho\right) \tag{48}
\end{align*}
$$

where

$$
\begin{align*}
& a=D_{T}+D_{A}^{\omega}  \tag{49a}\\
& b=2 \phi\left(D_{T}-D_{A}^{\omega}\right)  \tag{49b}\\
& \lambda=\phi D_{A}^{\omega} D_{T} \frac{1-\kappa^{2}}{1+\kappa^{2}}  \tag{49c}\\
& \xi=-8 \phi D_{A}^{\omega} D_{T} \frac{1-\kappa^{2}}{1+\kappa^{2}},  \tag{49d}\\
& k[\varrho]=D_{A}^{\omega} D_{T} \frac{1-\kappa^{2}}{1+\kappa^{2}}(-1+6 \phi \varrho(\mathbf{x}, t)), \tag{49e}
\end{align*}
$$

and $k[\varrho]=k_{0}+2 k_{1} \varrho(\mathbf{x}, t)$. Eq. (48) is known as the (deterministic) AMB+ 53 55, 111, and can be rearranged into the form

$$
\begin{equation*}
\frac{\partial}{\partial t} \varrho(\mathbf{x}, t)=-\nabla \cdot\left[-\nabla\left(\frac{\delta \mathcal{F}}{\delta \varrho}+\lambda(\nabla \varrho)^{2}\right)+\xi(\nabla \varrho)\left(\nabla^{2} \varrho\right)\right] \tag{50a}
\end{equation*}
$$

where

$$
\begin{equation*}
\mathcal{F}[\varrho]=\int \mathrm{d} \mathbf{r}\left(f_{0}[\varrho]+\frac{k[\varrho]}{2}(\nabla \varrho)^{2}\right) \tag{50b}
\end{equation*}
$$

is the free-energy functional and $f_{0}[\varrho]=a / 2 \varrho^{2}+b / 3 \varrho^{3}$ is the bulk free-energy density. Note that typically $\varrho^{\prime}=\varrho-\varrho_{\mathrm{MF}}$ is taken to be the order parameter, where $\varrho_{\mathrm{MF}}$ is the mean-field critical value of the density. If one does so, a term $\propto \varrho^{3}$ is forbidden by symmetry in $f_{0}$, but we instead work with the density $\varrho$ itself. Note that Eq. (50) was first written down based on phenomenologically accounting for systems with broken detailed-balance to lowest order terms in Refs. [53, 55].
2.5.3. First-principles expressions for field-theoretical parameters. The parameter $k[\varrho]$ in the free energy is known as the Cahn-Hilliard parameter [112]. When first introduced, this parameter was the minimal attempt in an equilibrium model to extend the bulk free energy $\mathcal{F}$ to further include density-gradient-induced inhomogeneities into the description. Via this very successful approach, field theories could nicely capture phase-separation dynamics in equilibrium models $[52,113]$. In the general formulation, $k[\varrho]$ is density-dependent, and a Taylor expansion to lowest order in the density gives $k[\varrho]=k_{0}+2 k_{1} \varrho$. The coefficients $k_{0}$ and $k_{1}$ are found in our model by comparing the first-principles time-evolution equation (47) with the phenomenological equation of the AMB $+(48)$. From an equilibrium perspective, it might appear surprising that from Eq. (49e) we find that $k_{0}<0$ for a non-chiral system $(\kappa=0)$ and thus also $k[\varrho]<0$ to lowest order. In an equilibrium field theory, this would lead to an unbounded free energy and the non-physical possibility of a system minimising its free energy by creating more and more interfaces due to phase separation. But for an active field theory such as the $\mathrm{AMB}+$, the time evolution is not solely governed by a free-energy structure. Further terms $\propto \lambda, \xi$ balance the free-energy governed evolution, and thus equilibrium intuition can fail. Note also that in our first-principles derivation for active systems $k[\varrho] \propto D_{A}^{\omega}$, and therefore this quantity vanishes as the model is approaching an equilibrium situation $\left(D_{A}^{\omega} \rightarrow 0\right)$. Finally, the observation of $k_{0}<0$ is consistent with other works on the AMB $+53,57$, but (active) chirality adds a new perspective, since here $k_{0}$ and $k_{1}$ change sign as $\kappa>1$.

The observation, that the coefficients which are induced by activity and interactions $\left(\lambda, \xi, k[\varrho] \propto \phi D_{A}^{\omega}\right)$ can change their sign as a function of chirality is rather surprising. From the Langevin dynamics and the integration procedures, we would have not expected that chirality and interactions could interplay such, that they lead to physical consequences. In the hard-core interacting scenario the angular coordinate is not altered by the excluded-volume interaction of the spatial coordinate, and therefore chirality does not affect the time-evolution of the full one-body PDF beyond the (trivial) interactionfree terms, as can be seen from Eq. (25). Any interplay of spatial and angular coordinates is only introduced in the projection on the hydrodynamic modes. We can nevertheless qualitatively justify why the change in the behaviour happens at $\kappa=1$. Similar to the rotational diffusion coefficient, which introduces a time scale in the system $\tau=\tau_{\text {diff }}=1 / D_{R}$, the active chirality introduces a time scale as well, namely, $\tau_{\text {act }}=1 / \omega$. These time scales represent the noise and the deterministic circular contribution to the active motion of the particle, respectively. Hence the parameter $\kappa=\omega / D_{R}=\tau_{\text {diff }} / \tau_{\text {act }}$ measures which contribution is dominating the motion of a particle, similar to what was recently reported in Ref. 105,114 . That means that $\kappa<1$ corresponds to a system, in which the diffusive motion dominates the active particle, whereas $\kappa>1$ corresponds to a deterministic-circular-motion determined motion, see also Fig. 3. Interestingly, when both effects are of equal magnitude, $\lambda, \xi, k[\varrho]=0$, the system again behaves as described by the effective diffusion dynamics of Eq. (43).

The phenomenological parameters $\lambda$ and $\xi$ represent the active generalisations of

Figure 3: For ACPs one can define the parameter $\kappa=\omega / D_{R}$, which is a measure of active chirality $\omega$ versus rotational diffusion $D_{R}$ of the particle. In a related context, this parameter is known as the oddness parameter [77, 89, 92, 94]. The characteristic parameters of the $\mathrm{AMB}+, \lambda,-\xi$ and $k[\varrho]$ all scale $\propto\left(1-\kappa^{2}\right) /\left(1+\kappa^{2}\right)$, see also Eqs. (49c) to (49e). Thus, they are positive as long as $|\omega|<D_{R}$, i.e., the circular motion is dominated by diffusion, and are negative for $|\omega|>D_{R}$, i.e., the motion is dominated by activity. Note that the sign of $\omega$ accounts for the clockwise or counterclockwise direction of the active chirality.
equilibrium Model B [51] $\left(\partial \varrho / \partial t=-\nabla \mathbf{J}_{\text {eq }}=\nabla(\delta \mathcal{F}[\varrho] / \delta \varrho)\right.$, where $\varrho$ is the conserved order parameter, $\mathbf{J}_{\text {eq }}$ the equilibrium (deterministic) current and $\mathcal{F}$ is the equilibrium free energy). Since this model was constructed on the basic principle of the system to obey detailed-balance, to describe active matter, this restriction had to be overcome. A first step in the development of active field theories was the so-called Active Model $B$ (AMB) 85, 115], where $\lambda \neq 0$ but $\xi=0$. This model still attracts interest as it represents the first step towards an active field theory [116, 117], but it was shown that even though quantitatively the coexisting liquid and vapour densities are changed, the AMB cannot report any quantitative changes in the coarsening dynamics as compared to the known dynamics found by phenomenologically introducing activity in the Model B [115]. Note that Eq. (43) as the lower order result of the closure scheme, has such a Model B structure with coefficients altered by activity.

The sought qualitative changes in the phase-separation dynamics of active matter could thereafter be found by the generalised AMB + where $\lambda \neq 0$ and additionally $\xi \neq 0$. Similarly to the AMB, the AMB+ as the most general isotropic model at this order goes beyond the typical free-energy structure of Model $B(\lambda \neq 0)$. For the AMB,
the $\lambda$-term defines a (local) non-equilibrium chemical potential $\mu_{\text {neq }}=\delta \mathcal{F} / \delta \varrho+\lambda(\nabla \varrho)^{2}$, since the current is still of a gradient form. For the AMB+ instead the $\xi$-induced current cannot be put into a gradient structure anymore and therefore allows for circulating realspace currents $\nabla \wedge \mathbf{J}_{\text {neq }} \propto \xi$. Further, as a result of the non-gradient structure of the current, the non-equilibrium chemical potential becomes non-local 53,54$]$ and therefore amounts to fundamental differences of AMB and AMB+. As these studies suggest, this non-locality seems to be a necessary ingredient to describe the behaviour of active matter from a field theoretical perspective.

Finally, it is interesting to note that as a result of our first principles approach, the AMB + appears as the most natural choice of an active field theory which relies on an expansion in terms of density gradients. We observe from Eqs. (49c) and (49d) that $\lambda=-8 \xi$. Thus, it is not reasonable to include one but leave out the other parameter in the field- theoretical description, similarly to what was pointed out recently [59]. We further observe that, as argued phenomenologically, both $\lambda, \xi \propto D_{T} D_{A}^{\omega}$, such that the AMB+ reduces to an interaction-corrected, passive diffusion equation for $D_{A}^{\omega} \rightarrow 0$. Interestingly, it also reduces to the non-equilibrium effective diffusion equation (43) as $D_{T} \rightarrow 0$, i.e., when the thermal motion becomes negligible compared to the activity. Lastly, as expected, $\lambda$ and $\xi$ are only present in an interacting system $(\lambda, \xi \propto \phi)$, since they are known to alter the phase-separation dynamics.

## 3. Conclusion

We here extended a geometric approach $[62,64,73,77]$ to deal with particle-particle interactions by restricting the domain of definition of their diffusing centrers. Forbidden overlaps of the particles correspond to forbidden areas in the domain, creating a configuration space with inner moving boundaries. Based on that we derived an effective time-evolution equation for the full one-body PDF. We proceeded by projecting the full one-body PDF onto its angular modes, which resulted in a coupled hierarchy of hydrodynamic modes. By scrutinising the underlying assumptions we turned the closure scheme into a perturbation problem and found effective time-evolution equations (fieldtheories) for the mean particle density.

One major result of our work is the following. We observed that this procedure provides us with first-principles access to the otherwise phenomenological parameters of field-theoretical descriptions of active matter. We find that, beyond an effective diffusive description, the microscopically best justified theory of a continuous model is the AMB+ [53,55]. This was also reported in another recent first-principles derivation of the AMB+ for non-chiral ABPs [57]. From a technical point of view, our work unravels the theoretical necessities of the regimes of validity to obtain such a coarsegrained model for the description of active matter. Specifically, we find that when neglecting the time evolution of higher modes such as polarisation or nematic order, in the so-called adiabatic limit, the AMB+ model is microscopically justified only in the limit of low Péclet numbers, i.e., when thermal diffusion dominates active motion.

Figure 4: We numerically solve the AMB+ dynamics of Eq. 50 with the coefficients given by Eq. (49) for different times on a periodic two-dimensional lattice (118]. We chose the system parameters for the passive and active diffusivity as $D_{T} / D_{0}=$ 1, $D_{A}^{0} / D_{0}=0.05$ rescaled by some reference diffusivity $D_{0}$, and the volume fraction as $\phi=0.1$. With this choice of parameters we stay within the regime of validity of our derived $\mathrm{AMB}+$ dynamics, i.e., $\mathrm{Pe}=\sqrt{2 D_{A}^{0} / D_{T}} \ll 1$ and $\phi \ll 1$. Starting from a random initial distribution, the density quickly relaxes to a homogeneous steady state $\varrho(\mathbf{x}, t)=\varrho_{0}=0.5$, where the white arrows indicate the direction of the normalised diffusive flux (note the different magnitudes of the density variation at different times). Different regions of active chirality $\kappa=\omega / D_{R}$ only affect the density relaxation at later times $(t=40,400)$, as only higher-order density gradient terms of the AMB+ are affected by the sign-change of the coefficients. In the plots, time is rescaled by the natural time scale $\tau=1 / D_{R}$ and space is measured in units of $\sqrt{D_{0} \tau}$.

Whether the microscopic justification for the AMB+ model can be extended to regimes of higher activity is a subject of future research.

The main prediction of this work is that active chirality has a non-trivial influence on the dynamics of the mean particle PDF $\varrho(\mathbf{x}, t)$. Even though in the simplest version of the ACP model chirality is not altered by particle interactions (see again the Langevin description in Eq. (11) and hence its effect on the full one-body level is rather superficial, it becomes most prominent when integrating out the angular dependence of the full onebody PDF $p(\mathbf{x}, \theta, t)$. We find that an odd tensor $73,94 \boldsymbol{\Gamma}^{-1} \sim(\mathbf{1}-\kappa \varepsilon)$ emerges, where chirality defines the off-diagonal elements $\kappa=\omega / D_{R}$. Powers of that tensor, and hence chirality, eventually, can change the sign of all activity-induced coefficients of the AMB+,
$\lambda$, and $\xi$, as well as the Cahn-Hilliard coefficient $k[\varrho]$. Restricted to the effective diffusion dynamics similar to Eq. (43) the alternative approach of Ref. 103] did not report this phenomenon, as their method to incorporate interactions assumes translational and rotational invariance and therefore can only treat chirality pertubatively. Whether the sign-change of the coefficients has implications for the phase-transition dynamics, however, cannot be addressed within our model due to its restricted validity to regimes away from phase transitions for particles with repulsive interactions. In the regime of validity of our AMB + model, numerical solutions of Eq. (50) with the parameters of Eqs. (49) only admit a homogeneous phase, see Fig. 4 .

The systematic analysis presented in this work allows us to further include the effect of nematic order on the time-evolution of the mean particle PDF, but it would amount to a field-theoretical description at an even higher order than the AMB+ (which is already at fourth order in density gradients). The AMB+ was recently shown to be deducible from such a (stable) higher-order model [119], where it was shown that the AMB+ itself is unstable for sufficiently high order parameters. We suspect a similar behaviour if one performed the corresponding closure scheme on the level of the nematic order in our theory, which we leave for future work.

Inspired by a rich behaviour of complex macroscopic phenomena in active matter, an additional step would be to directly couple the chirality to the spatial interaction of the particles 120,121 . Motivated from an orientation-dependent potential of the form $\hat{\mathbf{e}}\left(\theta_{i}\right) \cdot \hat{\mathbf{e}}\left(\theta_{j}\right)$ for the propulsion vectors of particles $i$ and $j$ [122], we could consider additional aligning interactions together with active chirality from an analytic perspective on the restricted domain resembling steric interactions. A recent work considered the numerical effects of such alignment for phenomena like motility-induced phase separation and the flocking of active chiral particles (95].

## Appendix A. Evaluation of integral (7)

In the main text, in Eq. (7) we are left with evaluating a boundary integral, in which integration and differentiation are with respect to different particle labels. Hence a use of the Gaussian divergence theorem is not possible straightforwardly. Instead, we use an extended version of the Reynolds transport theorem, which usually allows for the time-differentiation of an integral quantity, where the integration volume $V$ itself is timedependent $V=V(t)$. For an arbitrary space- and time-dependent function $f=f(\mathbf{x}, t)$,
the theorem in this context reads

$$
\begin{equation*}
\frac{\partial}{\partial t} \int_{V(t)} \mathrm{d} \mathbf{x} f=\int_{V(t)} \mathrm{d} \mathbf{x} \frac{\partial f}{\partial t}+\int_{\partial V(t)} \mathrm{dS}_{\mathbf{x}}\left(\mathbf{n} \cdot \mathbf{v}_{\partial V(t)}\right) f \tag{A.1}
\end{equation*}
$$

where $\mathbf{v}_{\partial V(t)}=\mathbf{v}_{\partial V(t)}(\mathbf{x}, t)$ is the velocity of an element of the moving boundary $\partial V(t)$ and $\mathrm{dS}_{\mathbf{x}} \mathbf{n}$ is the outward area element of the boundary at time $t$.

This theorem can be extended to cases, in which the integration volume $V$ is spacedependent ( $V=V(\mathbf{x})$, but of a constant shape) and we are interested in taking the divergence of the integral with respect to that coordinate $\mathbf{x}$. For a vector-valued function $\mathbf{f}=\mathbf{f}(\mathbf{x}, \mathbf{y}, t)$, the extended transport theorem reads

$$
\begin{equation*}
\nabla_{\mathbf{x}} \cdot \int_{V(\mathbf{x})} \mathrm{d} \mathbf{y} \mathbf{f}=\int_{V(\mathbf{x})} \mathrm{d} \mathbf{y} \nabla_{\mathbf{x}} \cdot \mathbf{f}+\int_{\partial V(\mathbf{x})} \mathrm{d} S_{\mathbf{y}} \mathbf{n}_{\mathbf{y}} \cdot \mathbf{f} \tag{A.2}
\end{equation*}
$$

The proof of this relation can be found in Ref. [77]. We will apply this theorem to the reduced configuration space $\Lambda\left(\chi_{1}\right)=\Omega \backslash \mathrm{B}_{\varepsilon_{d}}\left(\mathbf{x}_{1}\right) \times[0,2 \pi)$, where the spacedependence is on $\mathrm{B}_{\varepsilon_{d}}\left(\mathbf{x}_{1}\right)$, the disk of radius $\varepsilon_{d}$ centred at $\mathbf{x}_{1}$. Therefore, only $\partial \mathrm{B}_{\varepsilon_{d}}\left(\mathbf{x}_{1}\right)$ contributes a moving boundary, and hence a boundary integral in Eq. A.2. We now apply the extended Reynolds transport theorem to evaluate Eq. (7). Note here that $P_{2}(t)=P_{2}\left(\chi_{1}, \chi_{2}, t\right)$ for a shortness of notation. We find the result

$$
\begin{align*}
& \int_{\Lambda\left(\chi_{1}\right)} \mathrm{d} \chi_{2} \nabla_{\chi_{1}} \cdot\left[\mathbf{D} \nabla_{\chi_{1}}-\mathbf{f}\left(\theta_{1}\right)\right] P_{2}(t) \\
& =\nabla_{\chi_{1}} \cdot \int_{\Lambda\left(\chi_{1}\right)} \mathrm{d} \chi_{2}\left[\mathbf{D} \nabla_{\chi_{1}}-\mathbf{f}\left(\theta_{1}\right)\right] P_{2}(t) \\
& \quad-\int_{0}^{2 \pi} \mathrm{~d} \theta_{2} \int_{\partial \mathrm{B}_{\varepsilon_{d}\left(\mathbf{x}_{1}\right)}} \mathrm{dS}_{2} \mathbf{n}_{2} \cdot\left[D_{T} \nabla_{1}-v \hat{\mathbf{e}}\left(\theta_{1}\right)\right] P_{2}(t) . \tag{A.3}
\end{align*}
$$

The moving boundary only arises in the spatial part of $\chi_{1}=\left(\mathbf{x}_{1}, \theta_{1}\right)$, and thus we are only left with the spatial part of the diffusion matrix $\mathbf{D}=\operatorname{diag}\left(D_{T}, D_{T}, D_{R}\right)$ and drift term $\mathbf{f}\left(\theta_{1}\right)=\left(v \hat{\mathbf{e}}\left(\theta_{1}\right), \omega\right)^{\mathrm{T}}$. We again apply the extended theorem for the first term in the evaluated integral

$$
\begin{align*}
& \nabla_{\chi_{1}} \cdot \int_{\Lambda\left(\chi_{1}\right)} \mathrm{d} \chi_{2}\left[\mathbf{D} \nabla_{\chi_{1}} P_{2}(t)\right]=\nabla_{\chi_{1}} \cdot \mathbf{D} \nabla_{\chi_{1}} \int_{\Lambda\left(\chi_{1}\right)} \mathrm{d} \chi_{2} P_{2}(t) \\
& -\nabla_{1} \cdot \int_{0}^{2 \pi} \mathrm{~d} \theta_{2} \int_{\partial \mathrm{B}_{\varepsilon_{d}\left(\mathbf{x}_{1}\right)}} \mathrm{dS}_{2} \mathbf{n}_{2}\left[D_{T} P_{2}(t)\right] . \tag{A.4}
\end{align*}
$$

We are left with evaluating the originating boundary integral combined with the boundary integral of Eq. A.3). Therefore we jointly use the divergence theorem and the transport theorem, paying respect to the specific integration volumes in the following steps. First we apply the divergence theorem on the volume $\Omega \backslash \mathrm{B}_{\varepsilon_{d}}\left(\mathbf{x}_{1}\right)$ "backwards",

$$
\begin{align*}
& -\nabla_{1} \cdot \int_{0}^{2 \pi} \mathrm{~d} \theta_{2} \int_{\partial \mathrm{B}_{\varepsilon_{d}}\left(\mathbf{x}_{1}\right)} \mathrm{dS} \mathbf{2}_{2}\left[D_{T} P_{2}(t)\right]=-D_{T} \nabla_{1} \cdot \int_{\Lambda\left(\chi_{1}\right)} \mathrm{d} \chi_{2} \nabla_{2} P_{2}(t) \\
& +D_{T} \nabla_{1} \cdot \int_{0}^{2 \pi} \mathrm{~d} \theta_{2} \int_{\partial \Omega} \mathrm{dS}_{2} \mathbf{n}_{2} P_{2}(t) . \tag{A.5}
\end{align*}
$$

Using the generalised transport theorem, the first integral on the right-hand side of Eq. A.5) can be rewritten as

$$
\begin{align*}
& -D_{T} \nabla_{1} \cdot \int_{\Lambda\left(\chi_{1}\right)} \mathrm{d} \chi_{2} \nabla_{2} P_{2}(t)=-D_{T} \int_{\Lambda\left(\chi_{1}\right)} \mathrm{d} \chi_{2} \nabla_{1} \cdot \nabla_{2} P_{2}(t) \\
& -D_{T} \int_{0}^{2 \pi} \mathrm{~d} \theta_{2} \int_{\partial \mathrm{B}_{\varepsilon_{d}\left(\mathbf{x}_{1}\right)}} \mathrm{dS}_{2} \mathbf{n}_{2} \cdot \nabla_{2} P_{2}(t) \tag{A.6}
\end{align*}
$$

Note again here that only $\mathrm{B}_{\varepsilon_{d}}\left(\mathrm{x}_{1}\right)$ is space-dependent and thus contributes a boundary term in the generalised transport theorem. Since integration and differentiation are with respect to the same particle label in the first integral on the right-hand side of Eq. (A.6), we can apply the divergence theorem "forwards"

$$
\begin{align*}
& -D_{T} \int_{\Lambda\left(\chi_{1}\right)} \mathrm{d} \chi_{2} \nabla_{1} \cdot \nabla_{2} P_{2}(t)=-D_{T} \int_{0}^{2 \pi} \mathrm{~d} \theta_{2} \int_{\partial \Omega} \mathrm{dS} \mathrm{~S}_{2} \mathbf{n}_{2} \cdot \nabla_{1} P_{2}(t) \\
& \quad-D_{T} \int_{0}^{2 \pi} \mathrm{~d} \theta_{2} \int_{\partial \mathrm{B}_{\varepsilon_{d}}\left(\mathbf{x}_{1}\right)} \mathrm{dS}_{2} \mathbf{n}_{2} \cdot \nabla_{1} P_{2}(t) . \tag{A.7}
\end{align*}
$$

Note here that when applying the divergence theorem the box-boundary $\partial \Omega$ contributes a surface integral. As the box-boundary does not explicitly depend on $\mathbf{x}_{1}$, the partial differential operator $\nabla_{1}$ can be moved outside the integral (without creating another boundary term) and we observe that it cancels with the second integral on the righthand side of Eq. A.5). We are thus left with the two integrals on the inner boundary $\partial \mathrm{B}_{\varepsilon_{d}}\left(\mathrm{x}_{1}\right)$ and find that

$$
\begin{align*}
& -\nabla_{1} \cdot \int_{0}^{2 \pi} \mathrm{~d} \theta_{2} \int_{\partial \mathrm{B}_{\varepsilon_{d}}\left(\mathbf{x}_{1}\right)} \mathrm{dS} \mathbf{S}_{2}\left[D_{T} P_{2}(t)\right] \\
& =-D_{T} \int_{0}^{2 \pi} \mathrm{~d} \theta_{2} \int_{\partial \mathrm{B}_{\varepsilon_{d}}\left(\mathbf{x}_{1}\right)} \mathrm{dS}_{2} \mathbf{n}_{2} \cdot\left(\nabla_{1}+\nabla_{2}\right) P_{2}(t) \tag{A.8}
\end{align*}
$$

The rewriting of the boundary term of Eq. A.4 finally enables us to combine the result with the term in Eq. A.3). Using the definition of the full one-body PDF $p\left(\chi_{1}, t\right)=\int_{\Lambda\left(\chi_{1}\right)} \mathrm{d} \chi_{2} P_{2}\left(\chi_{1}, \chi_{2}, t\right)$, Eq. A.3 thus becomes

$$
\begin{align*}
& \int_{\Lambda\left(\chi_{1}\right)} \mathrm{d} \chi_{2} \nabla_{\chi_{1}} \cdot\left[\mathbf{D} \nabla_{\chi_{1}}-\mathbf{f}\left(\theta_{1}\right)\right] P_{2}(t)=\nabla_{\chi_{1}} \cdot\left[\mathbf{D} \nabla_{\chi_{1}}-\mathbf{f}\left(\theta_{1}\right)\right] p\left(\chi_{1}, t\right) \\
& \quad-\int_{\partial \mathrm{B}_{\varepsilon_{d}}\left(\mathbf{x}_{1}\right)} \mathrm{dS}_{2} \mathbf{n}_{2}\left[D_{T}\left(2 \nabla_{1}-\nabla_{2}\right)+v \hat{\mathbf{e}}\left(\theta_{1}\right)\right] P_{2}(t) \tag{A.9}
\end{align*}
$$

which constitutes the result of Eq. (7) in the main text.
