Clathrin-mediated endocytosis is the main pathway used by eukaryotic cells to take up extracellular material, but the dominant physical mechanisms driving this process are still elusive. Recently several high-resolution imaging techniques have been used on different cell lines to measure the geometrical properties of clathrin-coated pits over their whole lifetime. Here we first show that all datasets follow the same consensus pathway, which is well described by the recently introduced cooperative curvature model, which predicts a flat-to-curved transition at finite area, followed by linear growth and subsequent saturation of curvature. We then apply an energetic model for the composite of plasma membrane and clathrin coat to the consensus pathway to show that the dominant mechanism for invagination is coat stiffening, which results from cooperative interactions between the different clathrin molecules and progressively drives the system towards its intrinsic curvature. Our theory predicts that two length scales determine the time course of invagination, namely the patch size at which the flat-to-curved transition occurs and the final pit radius.

I. INTRODUCTION

Each biological cell is defined and protected by a plasma membrane, but also needs to transport nutrients or signaling molecules across it [1]. To take up extracellular material, eukaryotic cells have developed different uptake strategies [2]. Among these, clathrin-mediated endocytosis (CME) is the main uptake route and used mainly for particles in the range from 20 to 300 nm, which also includes many common viruses [3]. In order to bend the plasma membrane inwards and to form a transport vesicle, a hexagonal lattice made from the protein clathrin is assembled at the plasma membrane, which is punctuated by a few pentagons to generate curvature [4]. These networks are naturally formed by clathrin molecules, because they have the form of triskelia after assembly of three heavy chains, each decorated with one light chain. Clathrin triskelia feature multiple binding sites to each other as well as an intrinsic curvature [5]. Remarkably, clathrin triskelia can self-assemble without any additional factors into closed cages that resemble fullerenes, with twelve pentagons in a sea of hexagons [6]. In reconstitution assays with lipid vesicles, clathrin binds to the membrane through adapter proteins like AP180 and then deforms it [7]. In the cell, the situation under which clathrin lattices assemble is more complex, since here many more proteins participate in the assembly and invagination process [8]. In particular, an actin network can form around the growing pit, that can pull and push the invaginating membrane inwards [9, 10].

The exact time point at which curvature is generated during CME has been debated since many decades [11, 12]. Early work with cells supported the constant area model (CAM), in which clathrin triskelia first grow

into large flat patches, which then invaginate. In contrast, reconstitution experiments with lipids and clathrin tend to favor the constant curvature model (CCM), in which curvature is generated right from the start of the clathrin assembly [7]. Today it is accepted that the actual process is a mixture of both scenarios, with both area and curvature growing in time during CME. Recently several high resolution imaging techniques have been used to spatially resolve the time course of CME in mammalian cells [13–16]. Using electron tomography (ET) [13], high-speed atomic force microscopy (HS-AFM) [17] and super-resolution microscopy (SRM) [16], it has been shown that curvature starts to be generated only once around half of the final clathrin coat has been assembled. What all these techniques have in common is that snapshots are taken of clathrin coats that can be sorted according to the state of invagination, which is used as a surrogate for time. However, until now these different datasets have not been compared with each other. In particular, the HS-AFM data has not yet been evaluated as a function of pseudo-time.

Although their molecular architecture suggests that individual clathrin triskelia can independently generate coat curvature, in recent years it has become increasingly clear that coat invagination arises from the collective interaction of clathrin triskelia within the clathrin lattice. In particular, it has been shown that invagination is favored by exchange of the clathrin light chains [18], that clathrin assembly is facilitated on curved membranes [19–21] and that clathrin triskelia undergo conformational switches that increase curvature [22]. Moreover, dissection of the clathrin coat using AFM has demonstrated that the assembled lattice is elastically frustrated [17]. Recent experimental studies also highlighted the role of actin during coat invagination [9]. In particular, it has been suggested that in mammalian cells, polymerizing actin could drive the invagination of the clathrin coat by pushing on its edges [10]. Moreover, it has been dis-

FIG. 1. **Cooperative curvature model (CoopCM)**. (A) The clathrin coat is assumed to have the shape of a spherical cap with invagination angle θ , cap radius R , area A and edge length ϵ . Curvature $H = 1/R$ is therefore the same everywhere, but changes in time, as does the invagination angle θ . (B) Curvature H , (C) area A and (D) edge length ϵ as a function of invagination angle θ as predicted by the CoopCM, normalized to their maxima (for $H_0 = \gamma$). The invagination angle θ acts as surrogate for time.

cussed that coat rearrangements [23] or lattice vacancies [24] could facilitate the invagination process.

To provide a simple mathematical description of coat assembly and invagination, we have recently suggested a conceptually transparent and analytically solvable kinetic model, the cooperative curvature model (CoopCM), that gives excellent fits to the growth kinetics observed with SRM [16]. The CoopCM is based on only a few simple assumptions that are motivated by the experimental observations, namely that the growing pit resembles a spherical cap, that area growth occurs mainly at the rim and that curvature is generated everywhere in the lattice, but in a cooperative manner, until a preferred value is reached. Although this phenomenological approach is effective, it does not address the underlying mechanisms. In principle, different physical mechanisms can contribute to drive coat invagination, including generation of spontaneous curvature, coat stiffening and line tension [17, 25].

In this work, we first discuss the CoopCM in more detail and show explicitly why it predicts a flat-to-curved transition at finite coat area. We then combine experimental data from different high-resolution techniques and different mammalian cell lines with the CoopCM to demonstrate that the invagination pathway of clathrin coats follows a universal pathway that we term the con-

sensus pathway. We next combine this universal pathway with an energetic model for the composite of plasma membrane and clathrin coat. We find that CME could not proceed with a constant coat stiffness, as this would involve a prohibitively large energy penalty for the initially flat clathrin coat. Therefore coat stiffening has to occur over time; combined with the spontaneous curvature of the clathrin triskelia, this provides the dominant energetic contribution and drives invagination.

II. THE COOPERATIVE CURVATURE MODEL

Previously, we showed that the kinetics of the invagination of the clathrin coat is well described by the CoopCM [16]. In the following, we briefly summarize the model and the underlying main assumptions. Our main assumption is that the clathrin coat takes the shape of a spherical cap, as observed experimentally [13, 16], which means that it is characterized by only two quantities, namely the invagination angle θ and the cap radius R (Fig. 1A). The two most important geometrical quantities for kinetic and energetic models are the cap area A and the edge length ϵ , which for the spherical cap are $A = 2\pi R^2(1 - \cos\theta)$ and $\epsilon = 2\pi R \sin\theta$, respectively. It is important to note that the formula for the area of the

spherical cap includes the flat circular disk in the double limit when $\theta \rightarrow 0$ and at the same time $R \rightarrow \infty$ with the disk radius $R \sin \theta \approx R\theta$ remaining finite.

Instead of giving a fully dynamic description, we describe how the coat curvature $H = 1/R$ evolves with θ , which we use as a surrogate of time. The reason for this is that experimentally only snapshots of clathrin coats are taken, which, assuming that coat invagination is an irreversible process, can be ordered according to their opening angle θ . The assumption here is that curvature changes occur over the whole domain of the spherical cap, thus making H the dominant slow dynamic variable, while the coat area is controlled by an independent growth mechanism along the edge of the clathrin coat. Moreover, we assume that as soon as the coat area has reached a certain threshold, coat curvature H builds up with a constant rate γ , driven by the interactions of the clathrin triskelia, which includes the generation of pentagons.

As the clathrin coat invaginates, the generation of coat curvature eventually has to slow down, because the clathrin coat approaches the final coat curvature $H_0 = 1/R_0$, which is set by the curvature of the clathrin triskelia, interactions with other clathrin triskelia and interactions with adaptor and accessory proteins at the membrane [20, 23]. This coat curvature H_0 is expected to be smaller than the curvature of clathrin cages $H_c = 1/R_c$, which is determined solely by the curvature of the clathrin triskelia and the interactions between the other clathrin triskelia [5, 11]. R_c has been measured to be in the range 32.5 – 50 nm [7, 26]. For typical pit sizes (typical membrane radius 40 nm [13] plus 15 nm accounting for the thickness of the clathrin coat and its gap to the membrane [7, 27]) the expected value for R_0 is around 55 nm, which indeed is above the range for radii for the cages.

As the coat reaches the saturation curvature H_0 , the coat curvature will stop increasing and a stable steady state of invagination emerges. Therefore, this curvature acts as a control mechanism for the invagination and effectively sets the pit size. Since the curvature saturation only sets in at the late stage of the invagination process and curvature generation is cooperative, we assume that it is proportional to H^2 (rather than to H , see more discussion below). Together, we now have a simple evolution equation for the coat curvature as a function of the invagination angle

$$\frac{dH}{d\theta} = \gamma \left(1 - \frac{H^2}{H_0^2} \right). \quad (1)$$

With the initial condition $H(\theta = 0) = 0$ the solution to Eq. (1) is

$$H(\theta) = H_0 \tanh \left(\frac{\gamma}{H_0} \theta \right). \quad (2)$$

Consequently, the radius of the coat is defined as the inverse of the coat curvature $R(\theta) = 1/H(\theta)$, where $R_0 = 1/H_0$.

Earlier we have shown that the CoopCM can be formulated also as a fully dynamic description that predicts the characteristic square root dependence of curvature with time that was observed experimentally [16]. Until Section IV, we do not address time explicitly, because we first focus on the geometry of the system, which is sufficient to develop an energetic description. However, we have to clarify at which coat area the invagination process starts. As done earlier for the fully dynamical version of the CoopCM, we now make the assumption that area growth along the edge occurs independently of coat invagination, which includes the possibility that invagination starts at finite area. Therefore, we can solve the area of the spherical cap for coat curvature H and consider the coat curvature as a function of θ at fixed area A . We thus use the area formula to write $H = \sqrt{2\pi(1 - \cos \theta)/A}$, which is justified as long as $A > 0$. Expanding the coat curvature H for a patch with finite area $A > 0$ in θ around the flat state ($\theta = 0$) yields

$$H = \sqrt{\frac{\pi}{A}} \left(\theta - \frac{\theta^3}{24} \right) + \mathcal{O}(\theta^5) \quad (3)$$

which is justified as long as A changes on another time scale. To obtain a differential equation for the coat curvature, we assume that the derivative of coat curvature $dH/d\theta$ can be written as a polynomial in H . Following this idea we expand $dH/d\theta$ as a power series up to second order in H to take non-linear effects like cooperativity between clathrin triskelia into account. We get $dH/d\theta = c_0 - c_1 H - c_2 H^2$, where c_0, c_1 and c_2 are expansion coefficients. Now we demand that the ansatz is consistent with Eq. (3). By taking the derivative of Eq. (3), we find that the derivative depends only quadratically on θ . Using Eq. (3) also on the power series we see that $c_1 = 0$, as otherwise a linear term in θ would appear. Thus internal consistency of the theory implies that the non-linear saturation term of the CoopCM in Eq. (1) follows from the fact that coat invagination starts at a finite A , given by Eq. (3). We conclude that the CoopCM in fact predicts a flat-to-curved transition at finite coat area, in agreement with the recent experimental observations [16].

In order to determine the value of the coat area at which invagination starts, we examine the area of the spherical cap using the expression for the coat radius $R(\theta) = 1/H(\theta)$ (Eq. (2)) in the limit of a flat disk, i.e., $\theta \rightarrow 0$

$$\lim_{\theta \rightarrow 0} A = \lim_{\theta \rightarrow 0} 2\pi \left(\frac{R_0}{\tanh(\gamma R_0 \theta)} \right)^2 (1 - \cos \theta) = \frac{\pi}{\gamma^2}. \quad (4)$$

As a result, we recover the area of a circular disk. From Eq. (4) we also find a second, geometrical interpretation of γ as the inverse of the patch radius $R_T = 1/\gamma$ at which the invagination of the flat coat starts. In the limit when

the coat approaches maximum invagination, we get

$$\begin{aligned} \lim_{\theta \rightarrow \pi} A &= \lim_{\theta \rightarrow \pi} 2\pi \left(\frac{R_0}{\tanh(\gamma R_0 \theta)} \right)^2 (1 - \cos \theta) \\ &= 4\pi R_0^2 \coth^2(\gamma R_0 \pi). \end{aligned} \quad (5)$$

Thus, the lower bound for the area of the fully invaginated state is $A = 4\pi R_0^2$. From the expression, we deduce a second, geometrical interpretation of R_0 , as the radius of the fully invaginated clathrin coat, which is valid in good approximation if the flat-to-curved transition occurs at finite coat area. Compared to Eq. (1), Eqs. (4-5) suggest a complementary perspective on the CoopCM: The CoopCM interpolates between the finite coat area where the flat-to-curved transition occurs (with circular disk radius $R_T = 1/\gamma$) and the fully invaginated spherical coat area (with sphere radius $R_0 = 1/H_0$) in a purely geometric way, without any additional parameters.

We also note that the CCM is a limiting case of the CoopCM if $\gamma \rightarrow \infty$. The CAM is partially recovered from the CoopCM, when we demand $A(\theta = 0) = A(\theta = \pi)$, which is true for $\gamma R_0 = 0.4411$. In this case, the corresponding coat area varies by around 10% between $\theta = 0$ and $\theta = \pi$ along the domain. These considerations suggest that γR_0 can be considered as a measure that indicates how close the CoopCM is to the CCM ($\gamma R_0 \gg 1$) or to the CAM ($\gamma R_0 = 0.4411$).

To illustrate the universal pathway of coat invagination as predicted by the CoopCM, in Fig. 1 the curvature (B), area (C) and edge length (D) of the clathrin coat are plotted normalized to their maxima for $H_0 = \gamma$. Due to the normalization and the fact that we here use $H_0 = \gamma$, the shape of the curves for curvature, area and edge length are independent of the specific choice of H_0 and γ . Apart from the saturation behaviour in curvature, we see that invagination of the clathrin coat starts at a finite initial coat area and therefore also at a finite edge length. The edge length has a maximum in the vicinity of the equator.

III. THE CONSENSUS PATHWAY OF CME

We now use the CoopCM, in the form of Eq. (2), to fit experimental data sets of the coat curvature H as a function of the invagination angle θ that have been recorded using different experimental methods and different cell lines. We use ET data [13], HS-AFM data [17], and SRM data [16]. For the ET data, we converted the measured tip radius of membrane pits as a function of θ to give the coat curvature $H(\theta)$ assuming the geometry of a spherical cap. Similarly, for the HS-AFM data we converted the measured coat area as a function of the coat radius to give $H(\theta)$. For the SRM data, clathrin-coated pits with negative curvature values and curvature values exceeding a threshold were excluded from the analysis (c3T3: $H > 0.014 \text{ nm}^{-1}$, SK-MEL-2: $H > 0.016 \text{ nm}^{-1}$, U2OS: $H > 0.014 \text{ nm}^{-1}$), similar to what was previously

reported (note for U2OS: there was a typo in [16] for the threshold value), because these strongly curved pits lack endocytic marker AP2-GFP and might belong to the Golgi [16]. The HS-AFM data is used as kindly provided by the authors [17]. The different data sets, the rolling means, and the fits according to Eq. (2) are shown in Fig. 2. For the CoopCM, we determine two parameters from the fit, $R_0 = 1/H_0$ and γ , which are both documented in Tab. I.

When we compare the results of the fits of the CoopCM in Fig. 2 to the CCM with $H = C$, where C is a constant, and to the CAM with $H(\theta) = \sqrt{2\pi(1 - \cos \theta)}/A_0$, where A_0 is a constant, we find that the CoopCM agrees excellently with the data for all used imaging techniques and cell lines, and that it performs better than the CCM or the CAM. For the CoopCM, γR_0 is between 0.67 and 0.83, while the flat-to-curved transition ($A(\theta = 0)/A(\theta = \pi)$) occurs at around 35-52% of the final coat area (Tab. I). This finding is consistent with the interpretation that the CoopCM predicts a pathway of coat invagination which is inbetween the CCM ($\gamma R_0 \gg 1$) and the CAM ($\gamma R_0 = 0.4411$) and which agrees best with the data.

Interestingly, the scale of coat curvature shows differences between the different datasets. For SK-MEL-2 cells using ET in Fig. 2A, the curvature values reach around 0.02 nm^{-1} , the largest observed values. For PTK2 cells using HS-AFM in Fig. 2B, we observe intermediate values of coat curvature of around 0.015 nm^{-1} . For c3T3, SK-MEL-2 and U2OS cells using SRM in Fig. 2C-E, we find the smallest curvature values of around 0.01 nm^{-1} . Interestingly, the differences between the different cell lines using the same technique in Fig. 2C-E are smaller than the differences between different techniques using the same cell line in Fig. 2A and D. The finding can be corroborated when comparing the different values of the preferred coat radius R_0 in Tab. I.

It is natural to assume that this systematic discrepancy is caused by how the clathrin coats are imaged in the different techniques. In the ET data of Avinoam et al. [13], the radii of the membranes invaginated by the clathrin coats are measured. Therefore, we expect ET to give large values of curvature. In the HS-AFM data of Tagiltsev et al. [17], the curvature is measured in unroofed cells directly at the clathrin coat. Therefore, we expect intermediate values of coat curvatures for this techniques. In the SRM data of Mund et al. [16], the clathrin coat is labeled by polyclonal antibodies that bind to both clathrin heavy and light chains of permeabilized cells, with a potential preference to the intracellular side due to a higher density of binding sites. Therefore, we expect small values of coat curvature. These arguments explain why we observe that the values of coat curvature decrease from ET through HS-AFM to SRM (cf. Tab. I).

Since the kinetics of clathrin coat invagination seem to be very similar for all cell lines and techniques (cf. Fig. 2A-E), we decided to pool the data by combining the values from all measurements. Following our

FIG. 2. **Experimental data define a consensus pathway that agrees with the CoopCM.** (A-F) Curvature H as a function of invagination angle θ for different data sets. The rolling mean (red) and the fit of the CoopCM (solid black), the CCM (dashed black) and the CAM (dotted black) are shown. (A) Electron tomography (ET) data [13]. (B) High-speed atomic force microscopy (HS-AFM) data [17]. (C-E) Super-resolution microscopy (SRM) data from different cell lines [16]. (F) Pooled data from all datasets where the ET and SRM data are corrected for curvature. The results of the fits are documented in Tab. I.

previous reasoning and to exclude any bias in the available data, we corrected the measured data from ET by taking into account the thickness of the clathrin coat and its gap to the membrane. The corrected coat curvature is given by $H = 1/(1/H_{\text{pit}} + h_{\text{cc}})$, where H_{pit} is the mea-

sured pit curvature and $h_{\text{cc}} = 15 \text{ nm}$ is the estimated thickness correction [7]. Similarly, we corrected the measured data from SRM by taking into account the length of the antibodies. The corrected coat curvature is then given by $H = 1/(1/H_a - l_{\text{ca}})$, where H_a is the measured

TABLE I. Parameter values for fitting the CoopCM (Eq. (2)) to different data sets (cf. Fig. 2). The fitted values for the datasets of Mund et al. [16] agree with those reported in [16].

Reference	Method	Cell line	R_0 (nm)	γ (nm ⁻¹)	γR_0	$A(\theta = 0)/A(\theta = \pi)$ (%)
Avinoam [13]	ET	SK-MEL-2	41.6	0.0189	0.785	39.4

antibody-labeled coat curvature and $l_{ca} = 15$ nm is the estimated length of the clathrin antibody. The curvature-corrected pooled data and the result of the corresponding fit (cf. Tab. I) then define the consensus invagination pathway for clathrin coated pits (Fig. 2F). We see excellent agreement between experimental data and the CoopCM. We also find that the flat-to-curved transition occurs at around 50% of the final coat area. In the following we analyze the energetics of this consensus pathway.

IV. THE ENERGETICS OF CME

A. Energy-based model

To address the question which physical mechanisms dominate the invagination of clathrin coated pits, we now introduce a model that describes the energetics of the clathrin coat. We formulate the total energy of the composite of plasma membrane and clathrin coat by a generalized membrane energy [25] that includes the most relevant energetic contributions

$$\mathcal{H} = \int_{\text{mem}} [2\kappa H^2 + \sigma] dA + \int_{\text{coat}} [-\mu + 2\kappa_c(H - H_c)^2] dA + \zeta \mathcal{E}. \quad (6)$$

The first integral describes the bending and tension energies of the plasma membrane, where κ is the bending rigidity of the membrane, σ is the membrane tension and H is the mean membrane curvature. The membrane energy is integrated over both the coated and free membrane parts. For the tension energy, the integral gives the excess area of the membrane, i.e., the additional area compared to the flat state.

The second integral in Eq. (6) describes the polymerization and bending energies of the clathrin coat, where μ is the polymerization energy density, κ_c is the coat bending rigidity, and H_c is the preferred curvature of the coat. The coat energy is integrated only over the coated membrane parts. The preferred coat curvature is related to the preferred radius of the clathrin coat by $H_c = 1/R_c$. The last term is the line tension energy, where ζ is the line tension. The line tension energy could be due to unsaturated clathrin bonds, additional protein binding

at the edge of the clathrin coat or actin pushing on the edges.

The two integrals in principle should be evaluated over different neutral surfaces, namely the ones of membrane and coat, respectively, which have a typical distance of 15 nm from each other due to the gap layer of adaptor proteins and the finite thicknesses of the two layers. In order to formulate a transparent theory in the spirit of thin shell and surface Hamiltonian models, here we neglect this effect. This aspect of the model is closely related to the question of relevant model parameters; for example, the reported high values for coat rigidity typically apply for the composite including the gap, and not necessarily for the clathrin coat alone [27], as we will discuss below.

Since it has previously been shown that the energy of the free membrane contributes only up to 20% of the whole membrane energy [28], in the following we neglect these contributions and only consider the membrane of the coated part. Again we assume that the clathrin coat has the shape of a spherical cap. Moreover, we assume that the properties of the clathrin coat are constant along the whole domain. Thus the integration over the coat area in Eq. (6) is given by the area A . The energy of the composite then follows as

$$E(\theta) = 4\pi\kappa(1 - \cos\theta) + \frac{\sigma}{2}(1 - \cos\theta)A - \mu A + \zeta \mathcal{E} + 2\kappa_c(H(\theta) - H_c)^2 A, \quad (7)$$

where we used the membrane excess area $\Delta A = (1 - \cos\theta)A/2$. The first term does not depend on size due to the conformal invariance of the bending Hamiltonian without spontaneous curvature. From Fig. 2F, we know the consensus pathway of invagination. Based on this, we can now predict the different energy contributions in absolute terms by using the coat area $A = 2\pi R^2(1 - \cos\theta)$ and the coat edge length $\mathcal{E} = 2\pi R \sin\theta$ on Eq. (7).

The results are plotted in Fig. 3 for typical parameters values as summarized in Tab. II. For each subplot, we use the same reference values, but for the quantity under consideration, two extreme values are used to demonstrate the possible variations in energetics.

We first note that both the membrane bending energy (Fig. 3A) and the tension energy (Fig. 3B) monotonically increase as a function of θ . In contrast, the polymerization energy of the coat becomes more negative for

FIG. 3. **Different contributions to the energetics of the consensus pathway.** (A) Membrane bending energy. (B) Membrane tension energy. (C) Clathrin coat polymerization energy. (D) Line tension energy of the clathrin coat. (E and F) Clathrin coat bending energy. We use the references values given in Tab. II, but in addition vary the main quantity of each subplot as indicated in the legend.

increasing θ as the coat grows in size (Fig. 3C), in agreement with the general notion that release of free energy by polymerization is the main driving force for invagination. Because invagination starts with finite edge length, the line tension in Fig. 3D is approximately constant until the coat is halfway invaginated, before it rapidly decreases over the rest of the time course. This implies

that line tension does not play a driving role during the initial phases of invagination. Later it could become important for invagination, as known for vesicle formation from phase-separated membrane domains [32, 33], multilayered membranes [34] and sometimes discussed in the context of CME [25, 29, 35], but our results show that the corresponding energies are rather small compared to

FIG. 4. **Total energy for constant model parameters.** (A) Effect of constant polymerization energy density. (B) Effect of constant coat rigidity. The used parameter values are indicated either in the figure legends or in Tab. II.

the other contributions in Fig. 3. By far the largest energetic contribution comes from bending the clathrin coat (Fig. 3E). Because κ_c has been determined in independent experiments, there is no doubt that this value will be very high. We see that a shallow minimum is caused by the coat approaching its preferred curvature, which decreases the energy; because at the same time area is still increasing, the energy then rises again. For large enough values of the preferred coat radius R_c , the coat energy monotonically decreases (Fig. 3F). From these plots we conclude that the energetic competition between coat polymerization energy and coat rigidity strongly dominates the invagination pathway.

B. Total energy for static coat properties

Our goal is to predict the dominant physical mechanism for coat invagination and we assume that the overall invagination pathway has to be characterized by a well-defined downhill total energy landscape. Moreover, we expect that the flat state ($\theta = 0$) is characterized by a zero or negative total energy, so that flat growth is possible. Following our observation that polymerization energy and the stiffness of the coat are the dominant fac-

tors in coat invagination, we now investigate the effect of these two parameters. In Fig. 4A and B we plot the total energy as a function of θ , given by Eq. (7), for different polymerization energies μ and coat rigidities κ_c , respectively. We see that in all considered cases the total energy is positive over a significant part of the domain. Fig. 4A suggests that once started, a large enough polymerization energy could drive the invagination process over the whole lifetime, but that still the initial energy, associated with flat coat assembly, will be positive and hence make flat coat assembly at static parameter values unlikely. Fig. 4B indicates that the coat rigidity always renders the total energy positive for small values of θ . We conclude that the large positive value of the coat bending energy for small values of θ makes flat clathrin coat assembly energetically costly and therefore potentially impossible. Thus the system in the initial stages should rather be characterized by small coat bending rigidity. On the other hand, in the late stages the coat bending rigidity should be high in order to enforce the preferred curvature. This suggests that coat bending rigidity might be time-dependent.

C. Total energy for dynamic coat properties

Up to now we have seen that constant parameter values for coat polymerization energy, line tension, coat rigidity and preferred coat curvature do not lead to a negative and monotonically decreasing total energy. Thus the energetic description of Eq. (7) is incomplete and we hypothesize that the clathrin coat is still plastic during coat invagination. Therefore we now turn to the possibility that the model parameters have their own dynamics; at the same time, however, we have to make sure that our CoopCM still remains valid despite these changes.

In order to expand the dynamic description, we assume that the invagination pathway of the coat follows from

TABLE II. Model parameters. If not indicated differently, we use the reference value. NB: The reference value for the line tension is estimated in [29] for a lipid domain in the plasma membrane.

Parameter	Typical range	Reference value
Mem. rigid. κ	13 – 25 $k_B T$ [7, 30]	15 $k_B T$ [17]
Mem. tens. σ	$4.1 - 14 \cdot 10^{-5}$ N/m [17, 31]	$4.1 \cdot 10^{-5}$ N/m [17]

overdamped dynamics [36]

$$\alpha \frac{\partial H}{\partial t} = -\frac{\partial E}{\partial H}. \quad (8)$$

To make Eq. (8) dimensionally consistent, the friction coefficient α needs to carry the unit of energy times area and time. Since the only relevant energy and area in our problem are the coat rigidity κ_c and the coat area A , we assume $\alpha \sim \kappa_c A$. Moreover, we introduce the invagination rate k_i for dimensional reasons with $\alpha \sim 1/k_i$. The assumption makes intuitively sense, since coat friction increases with a stiffer and larger coat that is invaginated at a smaller rate, i.e., over a longer time. Moreover, we expect that $\alpha \sim \theta$ to incorporate the notion that friction increases during the invagination of the clathrin coat. In order to simplify Eq. (8), we now make use of the chain rule and obtain

$$\alpha \frac{\partial H}{\partial \theta} \frac{\partial \theta}{\partial t} = -\frac{\partial E}{\partial H}, \quad (9)$$

with $\alpha = \kappa_c A \theta / k_i$. In order to find an expression for $\partial \theta / \partial t$, we use the underlying dynamic assumption of the CoopCM, namely that the area A of the clathrin coats grows along the edge \mathcal{E} by addition of new triskelia with the growth speed k_{on} [16]

$$\frac{\partial A}{\partial t} = k_{\text{on}} \mathcal{E}. \quad (10)$$

Using once again the assumption that the clathrin coat takes the shape of a spherical cap, we can simplify Eq. (10) to get

$$2\dot{R} \tan \frac{\theta}{2} + R\dot{\theta} = k_{\text{on}}. \quad (11)$$

We then use the inverse of Eq. (2), its derivative and the chain rule to simplify Eq. (11) which leads to

$$\dot{\theta} = k_{\text{on}} \frac{1}{2 \frac{\partial R(\theta)}{\partial \theta} \tan \frac{\theta}{2} + R(\theta)}. \quad (12)$$

After expanding Eq. (12) up to leading order in θ we find

$$\dot{\theta} = k_g \frac{1}{\theta}, \quad (13)$$

with the rate of growth $k_g = 12\gamma k_{\text{on}} / (8\gamma^2 R_0^2 - 1)$, which carries the unit of 1s^{-1} . Now we can put everything together and obtain

$$\frac{\partial H}{\partial \theta} = -\frac{k_i}{k_g} \frac{1}{A \kappa_c} \frac{\partial E}{\partial H}. \quad (14)$$

In Eq. (14) the ratio of the invagination rate and the growth rate k_i/k_g defines a number that scales the dynamics. Since we have no means to determine those rates from the structural data we analyze, we consider k_i/k_g as a free parameter.

The particular form of the second term of the prefactor suggests the assumption that we can neglect all energetic contributions except of the polymerization energy and coat rigidity on the right hand side of Eq. (14). When all energy contributions are normalized by κ_c , all energy contributions except for the polymerization energy and the coat bending energy are rendered negligible, compare Fig. 3. Since the coat polymerization energy and the coat rigidity are the relevant quantities that drive coat invagination, we ask under which assumption we can get the CoopCM from these two terms. Therefore, we only consider the polymerization and coat energy in Eq. (7) and assume $\mu(H)$ and $\kappa(H)$ to depend on the degree of invagination. From Eq. (14) we obtain

$$\frac{\partial H}{\partial \theta} = -\frac{k_i}{k_g} \frac{1}{A \kappa_c} \frac{\partial}{\partial H} (-\mu(H)A + 2\kappa_c(H)(H - H_c)^2 A). \quad (15)$$

We note that we assume that the coat area A grows by addition of triskelia over the edge of the coat, independent of H . In order to bring Eq. (15) to the same functional form as the CoopCM, given by Eq. (1), and to avoid any internal inconsistency within the model framework, the simplest possible assumption is that the polymerization energy increases linearly with the curvature. Moreover, we must assume that the clathrin coat stiffens with an exponent of 3. We then have

$$\mu(H) = \frac{\mu}{2} \left(1 + \frac{H}{H_c}\right), \quad (16)$$

$$\kappa_c(H) = \kappa_c \left(\frac{H}{H_c}\right)^3. \quad (17)$$

The assumption of an initially weak coat seems to be required to allow initial curvature generation. Later, the increase in this value reinforces the invagination because it forces the system to adapt the inherent curvature of the mature lattice.

In principle, the dynamics of CME could also change the preferred coat curvature H_c . Making H_c dependent on coat curvature would have similar effects as making κ_c dependent on coat curvature. However, all possible sources of coat stiffening such as rearrangements in the clathrin coat or conformational changes in a clathrin triskelion will affect κ_c , too, as it sets the scale of the coat energy. Therefore, we here consider κ_c to be dependent on coat curvature, whereas H_c is assumed to be fixed by the geometry of the clathrin triskelion.

The functional form from above is the simplest one that can be directly linked to the CoopCM. Using Eqs. (16-17) on Eq. (15), we get in leading order

$$\frac{\partial H}{\partial \theta} = \frac{k_i}{k_g} \frac{\mu}{2\kappa_c H_c} \left(1 - \frac{12\kappa_c}{\mu} H^2\right). \quad (18)$$

By comparing the coefficients in Eq. (1) and Eq. (18), we can link the energetic description to the CoopCM and therefore gain a more mechanistic understanding of this

FIG. 5. **Total energy for time-varying model parameters.** (A) The total energy including all energy contributions as predicted by the energetic model according to Eqs. (16-17) using the consensus invagination pathway of Fig. 2F. The used parameter values are indicated either in the figure legend or in Tab. II. (B) The total energy including all energy contributions as predicted by the energetic model according to Eqs. (16-17) using the consensus invagination pathway of Fig. 2F, the pathway with the smallest pits (cf. Fig. 2A) and the pathway with the largest pits (cf. Fig. 2C). Parameter values used are indicated in Tab. II. (C) Flat-to-curved transition predicted for R_c , R_0 , k_g and k_i . Inset: The clathrin coat undergoes a flat-to-curved transition if $\xi \leq 1$.

initially kinetic model

$$H_0 = \sqrt{\frac{\mu}{12\kappa_c}}, \quad (19)$$

$$\gamma = \frac{k_i}{k_g} \frac{\mu}{2\kappa_c H_c}. \quad (20)$$

Using the fitted value of $R_0 = 63.2$ nm and the polymerization energy $\mu = 0.56$ mJ m⁻², we predict $\kappa_c = 45$ k_BT from Eq. (19). Compared to the typical value of coat rigidity in Tab. II, our predicted value of κ_c is too small by a factor of 6 to 7, likely due to simplifications in our theory and the assumed functional form of Eqs. (16-17). In particular, a different curvature scale instead of H_c or higher order terms could contribute to coat stiffening. However, it is also possible that the experimentally determined value of κ_c is too high, especially because it usually includes the contributions of the mechanics of the gap layer [27]. In addition, using the fitted value of $\gamma = 0.0110$ nm⁻¹, the coat rigidity of $\kappa_c = 45$ k_BT and the coat radius of $R_c = 40$ nm we predict $k_g/k_i = 5.5$ from Eq. (20). Our predicted value for k_g/k_i indicates that the invagination of the clathrin coat is slower compared to growth, which makes intuitive sense and suggests that the coat closes due to growth rather than bending.

In Fig. 5A we plot Eq. (7) with varying polymerization energy and coat rigidity according to Eqs. (16-17) for the parameters in Tab. II and $\kappa_c = 45$ k_BT. For both parameter combinations, the total energy is negative and monotonically decreasing as a function of θ , as it should be in a physical description of CME. The result justifies our approach and suggests that polymerization energy and coat rigidity indeed dynamically increase during coat invagination.

We also can check now whether the suggested mechanism is universal in the sense that in all cell lines, the total energy decreases. We therefore turn again towards the results of the fit of the CoopCM and plot the total energies according to Eqs. (7), (16) and (17) as a

function θ for the parameters that produce the smallest (Fig. 2A) and largest pits (Fig. 2C). The results are shown in (Fig. 5B) together with the pooled data for the parameters of Tab. II. Although there are differences between the different cell lines, in all three cases the mechanism of coat stiffening predicts the invagination of the clathrin coat.

We finally predict the time course of the invagination of the clathrin coat. The flat-to-curved transition occurs when the area of the coat at the transition, πR_T^2 , is smaller than the final coat area, $4\pi R_0^2$, i.e., $\pi R_T^2 \leq 4\pi R_0^2$. Otherwise the clathrin coat grows flat. From the inequality, we deduce a dimensionless parameter $\xi = R_T/(2R_0)$ that predicts the flat-to-curved transition if $\xi \leq 1$, and flat growth otherwise (Fig. 5C, inset). We connect the invagination radius $R_T = 2k_g\kappa_c/(k_i\mu R_c)$, to the energetic parameters by using Eq. (20) and the final coat radius $R_0 = \sqrt{12\kappa_c/\mu}$ to the energetic parameters by using Eq. (19). Using these expressions on the condition of the flat-to-curved transition, we can thus relate the time course of invagination of the clathrin coat to the kinetic parameters, $k_g/k_i \leq 12R_c/R_0$, which is illustrated in Fig. 5C. We conclude that the time course of invagination, parameterized by coat growth and invagination is determined by two length scales, the patch radius at which the flat-to-curved transition occurs and the final pit radius.

V. DISCUSSION

In this work, we investigated the invagination pathway of clathrin coats. We combined our recently developed CoopCM with datasets from different cell lines and high-resolution imaging techniques (ET [13], HS-AFM [17] and SRM [16]). We found that the CoopCM gives excellent fits to the various datasets. Comparing the trajectories of the different datasets by means of the CoopCM, we found very similar invagination behavior. We concluded that clathrin coats follow a consensus invagination path-

way described by the CoopCM. The model suggests that the dynamics of invagination is strongly determined by cooperative generation of curvature in the clathrin lattice. One very important result from both model and experiments is that a flat-to-curved transition occurs at finite coat area.

We then combined the consensus pathway and the CoopCM with an energetic model for the composite of membrane and coat. Our main result was that the energy related to coat stiffness dominates all other contributions. Moreover the flat-to-curved transition implies that the invagination process is not possible for energetic reasons if the coat stiffness is always at the high values reported experimentally for the later stages of the pits. Therefore, we conclude that coat stiffness has to start at low values and to dynamically increase during invagination. We showed that the CoopCM can be derived from the energetic model when assuming that the coat polymerization energy increases linearly with coat curvature and the clathrin coat stiffens with a power law exponent of three with coat curvature.

We note that a power law exponent of three also relates bending stiffness and thickness of thin sheets, suggesting that effective thickness might grow linear with curvature. In practise, this viewpoint of continuum mechanics might however be too naive, because clathrin lattices have very specific discrete architectures. Rather, this prediction of our theory should be tested experimentally. Our prediction that the polymerization energy of the clathrin coat increases linearly with the curvature of the coat is consistent with experiments and theory predicting that clathrin assembly is stabilized on curved surfaces and that clathrin triskelia in curved coats contain more energy than in flat clathrin lattices [20, 37]. In fact, the possibility of a curvature-dependent polymerization energy has been discussed previously [30]. Possible driving factors for coat stiffening and increase of the effective thickness on a more microscopic level are accumulation of phosphorylated clathrin light chains [18], conformational changes in clathrin triskelia [22], rearrangements within the coat or mending of lattice defects [23], filling up lattice vacancies [24], release of elastic energy within the coat [17], increasing the density of the clathrin coat [38], solidification of the coat [29, 39], changing clathrin to AP2 adapter ratio during coat assembly [14], the organized binding of clathrin triskelia to adaptor clusters [40], mechanics of the coupling between membrane and clathrin coat through adapter proteins [27], and the stabilization of membrane curvature by clathrin in a ratchet-like manner [21].

All these mechanisms require flexibility and weak interactions within the coat during invagination initially. Lattice rearrangements seem plausible, given that the coat shows triskelia exchange in the flat state [13, 41] but also can disassemble fast once it is complete [8]. The notion of weak interactions is supported by the fact that the legs of clathrin triskelia are flexible and bind only weakly to each other [42]. Moreover, clathrin triskelia

are not perfectly aligned with respect to each other even in curved configurations [5].

The stiffening of the clathrin coat could be complemented by an increasing line tension ζ , for example by polymerizing actin pushing from the periphery of the coat [9, 10]. However, our data also shows that this might be dispensable under normal conditions, in line with previous experiments [43].

It will require future work to dissect how exactly the coat stiffening occurs. In principle this could happen in a continuous way, similar to releasing elastic energy within the coat [17], or in a discrete or ratchet-like way, for example due to conformational changes in the clathrin triskelia, rearrangements within the clathrin coat [22, 23], or by filling up lattice vacancies [24]. Therefore, experimentally the CoopCM could be tested by studying the thickness, the density or the mobility of single triskelia within the clathrin coat as a function of time.

The notion of coat stiffening might be related to the ongoing discussion whether clathrin can generate membrane curvature alone [44] or whether it is only stabilising membrane curvature generated by adaptors and accessory protein [21, 45]. If membrane curvature was generated mostly by adaptor proteins, clathrin could stabilize the constant membrane curvature and the clathrin coat would immediately grow in a stiff configuration. However, if membrane curvature was mostly generated by clathrin, the coat curvature would increase during assembly because the clathrin coat stiffens. We speculate that coat stiffening occurs when the ability to generate membrane curvature by other proteins is insufficient. If so, clathrin assembly and coat stiffening could then drive membrane invagination. If coat stiffening is dispensable because coat curvature is generated by other proteins, this notion could also explain the seemingly conflicting experimental findings that report that clathrin coat invagination follows a model different from the flat-to-curved model [15, 46, 47].

To conclude, our results imply that the clathrin coat is more plastic during coat invagination than formerly appreciated and dynamically stiffens during coat invagination.

ACKNOWLEDGEMENTS

We thank Markus Mund, Aline Tschanz and Jonas Ries for helpful discussions and a critical reading of the manuscript. We also kindly acknowledge Simon Scheuring for providing the HS-AFM data for the analysis of clathrin coat invagination. We thank the reviewers of a previous version of this manuscript for useful feedback that helped us to improve this work. F.F. acknowledges financial support by the NOMIS foundation. U.S.S. was supported by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) under project number 240245660 (SFB 1129).
