## ABSTRACT

Using ‘spatially’ resolved spectroscopy, we investigated the characteristics and different modes of formation of stars in elliptical galaxies. We identified an unusual population of 59 star-forming elliptical (SF-E) galaxies in SDSS-MaNGA, our primary sample. To identify these rare star-forming ellipticals, we combined GSWLC-A2 containing outputs of stellar population synthesis models with morphological results from the deep-learning catalogue and resolved and integrated properties from the MaNGA Pipe3D value-added catalogue. We have also constructed two control samples of star-forming spirals (SF-Sps; 2419 galaxies) and quenched ellipticals (Q-Es; 684 galaxies) to compare with our primary sample of SF-Es. H $\alpha$  emission line flux of SF-Es is similar to spiral galaxies. The D4000 spectral index indicates that SF-Es have a mixture of old and young stellar populations. Mass-weighted stellar age and metallicity for the SF-Es are lower than the Q-Es. 67% of stellar and gas velocity maps of the primary sample show signs of kinematic disturbance. All of these indicate that SF-Es have acquired metal-poor gas through recent mergers or interactions with other galaxies and are forming a new generation of stars. Further, we subdivide our primary sample of SF-Es into four classes based on their  $B/T$  and  $\lambda_{re}$ . These four classes have their distinct evolutionary history and modes of formation. Based on these results, we suggest that the Hubble diagram does not accurately capture galaxy evolution processes, and we need a revised morphology diagram like the comb morphology diagram to get a complete picture of the galaxy evolution processes.

**Keywords:** galaxies: evolution — galaxies: star formation — galaxies: structure — galaxies: kinematics

## 1. INTRODUCTION

Galaxies are gravitationally bound systems of stars, interstellar gas, dust and dark matter. Galaxies are characterised by several global properties: luminosity, stellar mass ( $M_*$ ), morphology, size, star-formation rate (SFR), molecular/atomic/ionised gas content, environmental density, bulge to total luminosity ratio ( $B/T$ ), etc. These properties, when measured quantitatively, constitute a multidimensional parameter space. The distribution of galaxies in this space is not random, as many of these parameters are correlated with each other and manifest as scaling relations. Some of the well-

known scaling relations are the colour-magnitude relation (Sandage & Visvanathan 1978), the Tully-Fisher relation (Tully & Fisher 1977), the Fundamental Plane (Djorgovski & Davis 1987; Dressler et al. 1987) and the size-magnitude relation (Romanishin 1986). By studying these correlations while paying particular attention to galaxies that are outliers from the overall trend, we can gain insight into the galaxy formation and evolution processes responsible for these correlations.

With large-area galaxy surveys, like the Sloan Digital Sky Survey (SDSS; York et al. 2000), researchers found that in the nearby Universe, there is a bimodal distribution of galaxies on the colour-magnitude diagram (Stratova et al. 2001; Kauffmann et al. 2003; Baldry et al. 2004, 2006). There are the ‘blue cloud’ galaxies with active star formation and the ‘red sequence’ galaxies, which evolve passively, with little or no current star forma-

pbiswas@ncra.tifr.res.in

yogesh@ncra.tifr.res.in

tion. The galaxies in the region between these two populations are termed the ‘green valley’ galaxies (Wyder et al. 2007). Green valley galaxies are believed to be undergoing quenching of star formation (Salim et al. 2007) and are in the transition zone between the blue cloud and the red sequence (Wyder et al. 2007; Schiminovich et al. 2007; Mendez et al. 2011). Based on visual morphologies, galaxies are broadly classified as spirals (Sps), lenticulars (S0s), ellipticals (Es) and irregulars (Hubble 1926a). Many physical parameters discussed above correlate strongly with galaxy morphology, e.g. the SFR, which is high for Sps and low for Es (Kennicutt 1998).

Further, the star-forming main sequence (SFMS) refers to the tight relationship observed between the  $M_*$  and SFR of star-forming galaxies. This SFMS is observed in the local (Brinchmann et al. 2004; Salim et al. 2007) as well as the high redshift Universe up to  $z \sim 5$  (Daddi et al. 2007; Elbaz et al. 2007; Santini et al. 2017). Galaxies can deviate from the SFMS due to various physical processes, leading to the quenching of star formation. The exact physical processes behind the quenching of galaxies are unknown and often debated in the literature. Researchers invoke various mechanisms to explain quenching in star-forming galaxies, and morphological quenching is one of the strong candidate mechanisms (Martig et al. 2009). Late-type galaxies (LTGs: Sps) belong to the blue sequence and are highly star-forming. On the contrary, early-type galaxies (ETGs: Es and S0s) are red and quenched. ETGs are massive, reside in dense environments, have low gas content, often harbour strong AGNs (Active Galactic Nuclei) and have a merger-rich evolutionary history. All of these characteristics could contribute to star formation quenching in these galaxies.

Early-type galaxies are usually passive and red. However, a number of studies have recently uncovered an actively star-forming population of early-type galaxies. Schawinski et al. (2009) reported 204 blue early-type galaxies having SFR between  $0.5$  to  $50 \text{ M}_\odot \text{ yr}^{-1}$  in SDSS Data Release 6 (DR6) at  $0.02 < z < 0.05$ . For visual morphology, they used the Galaxy Zoo catalogue and  $u - r$  colours as a proxy for the SFR. They also found that blue early-type galaxies reside in lower-density regions than early-type red galaxies, constituting nearly 5% of the early-type population in the nearby universe. Although this particular class of galaxy is scarce, their presence raises pointed questions about our understanding of early-type galaxies.

There have been a number of efforts in the literature to try to understand the origin and characteristics of star-forming ETGs. George & Zingade (2015); George (2017) studied a sample of 55 star-forming early-type galaxies

and argued that recent minor mergers or interactions with gas-rich nearby galaxies could be responsible for the star formation in these galaxies. Once the acquired gas is depleted, these galaxies will evolve as standard passive ellipticals. In another study using  $NUV - r$  colour ( $NUV - r \leq 5.0$  as the selection criterion for star-forming galaxies), Jeong et al. (2021) identified recent star formation in the early-type galaxies and found that 7.7% of the sample galaxies have recent star formation. Investigation of the metal abundance in these galaxies shows that early-type galaxies with recent star formation are younger and more metal-poor than quiescent early-type galaxies. This suggests that these galaxies acquired metal-poor gas due to recent mergers or interactions with other galaxies.

Kaviraj et al. (2009) compared synthetic photometry from numerical simulations of minor mergers with UV colours from nearby ( $0.05 < z < 0.06$ ) early-type galaxies. The simulations were performed with merger progenitors with reasonable assumptions about ages, dust properties, and metallicities. The study indicated that minor mergers are a potent mechanism behind the large UV scatter and low-level star formation in early-type galaxies.

There are also a few studies on star-forming S0s trying to understand the different formation mechanisms of these galaxies. In the SDSS-MaNGA (Sloan Digital Sky Survey - Mapping Nearby Galaxies at Apache Point Observatory; Bundy et al. 2015; Blanton et al. 2017), Rathore et al. (2022) identified a sample of 120 star-forming S0s (SF-S0s). They found that the population of SF-S0s is abundant at lower stellar masses but sharply decreases above  $10^{10} \text{ M}_\odot$ . SFR surface density and specific star formation rate (sSFR) radial profiles show that the star formation in SF-S0s is comparable to the star-forming spirals (SF-Sps) but centrally dominated and decreases with the distance from the centre. By visually inspecting the stellar and gas velocity maps, they found that more than 50% SF-S0s are kinematically unsettled, possibly indicating signs of disturbance due to recent mergers rejuvenating the star formation. Another study by Xu et al. (2021) tried to understand the environmental dependence of the formation mechanism of SF-S0s. They argued that the SF-S0s in the groups are possibly the successors of fading spirals. However, in the field, S0s could have ignited their star formation through minor mergers providing metal-poor gas.

From the above discussion, it is clear that any sample of star-forming ETGs may not be a homogeneous class of objects. Different formation mechanisms could be responsible, and their relative abundance and global properties depend strongly on several parameters like

stellar mass and environment. In this work, we study a rare class of starforming ellipticals (SF-Es) in the nearby universe ( $z < 0.1$ ) using the SDSS-MaNGA Integral Field Spectroscopy (IFS) survey. Being an IFS survey, MaNGA provides spatially resolved spectroscopy across the two-dimensional image of the galaxies. This enables us to study different properties of the galaxies as well as their stellar population on spatially resolved scales. For a deeper understanding, we also compare the similarities and differences between star-forming ellipticals and two control samples of star-forming spirals and typical quenched ellipticals. This comparison could shed light on the different modes of formation of star-forming ellipticals.

This paper is organized as follows: We describe the sample selection in Section 2 along with the MaNGA survey, the different catalogues used, the selection criteria, and some of the global properties of our three samples. In Section 3, we present our main results. The results of the whole work and the different formation scenarios of the SF-Es are discussed in Section 4. We summarize the study and list the main conclusions in Section 5. Throughout, we use the  $\Lambda$ CDM cosmology with parameters  $H_0 = 67.8 \text{ km s}^{-1} \text{ Mpc}^{-1}$ ,  $\Omega_\Lambda = 0.69$  and  $\Omega_m = 0.31$  (Planck13 cosmology; Planck Collaboration et al. 2014).

## 2. SAMPLE SELECTION AND CHARACTERISATION

This section describes the sample selection criteria for the primary sample and the two control samples. We describe briefly the MaNGA survey, the Pipe3D pipeline, and all the catalogues we use in this study. We also briefly discuss each sample and some of its global properties.

### 2.1. The data and sample selection criteria

#### 2.1.1. The SDSS-MaNGA galaxy survey

The MaNGA survey is an SDSS-IV project (Blanton et al. 2017) that has observed over 10,000 galaxies from 2014 to 2020 (Bundy et al. 2015; Drory et al. 2015; Abdurro'uf et al. 2022). It uses the SDSS 2.5 m telescope at APO (Apache Point Observatory; Gunn et al. 2006) and the BOSS (Baryon Oscillation Sky Survey; Smee et al. 2013) spectrographs with continuous wavelength coverage from 3600-10300 Å. This is an IFS survey with fibres bundled into a distribution of several Integral Field Units (IFUs) of different sizes, which are tightly packed hexagonal arrays of fibres that deliver spatially resolved spectroscopy of each galaxy. The MaNGA survey has complicated selection criteria driven by scientific reasons to enhance the utility of the sample galaxies. The total

MaNGA sample consists of three main subsamples. The first one is the Primary sample, which has a flat distribution in K-corrected  $i$ -band absolute magnitude ( $M_i$ ) with coverage to  $1.5 R_e$  (r-band effective radius along the major axis). The Secondary sample also has a flat distribution in  $M_i$  but is covered by the IFUs to  $2.5 R_e$ . Finally, a sample of galaxies were selected to add galaxies in the underrepresented regions of  $NUV - i$  versus  $M_i$  colour-magnitude plane in the primary sample called the Colour-Enhanced sample with coverage to  $1.5 R_e$ . The Primary and the Colour-Enhanced sample together form the Primary+ sample, which is 2/3 of the whole sample, and the remaining 1/3 is the Secondary sample. Since the survey is designed to have a flat number density in  $M_i$  (proxy of the stellar mass) and flattened in colour for the Colour-Enhanced sample, it has strong selection biases. It also has technical biases because of the different IFU sizes and constraints on their allocations. These biases affect the statistical analysis of any population of galaxies. To carry out statistical analysis, it becomes essential to use the volume weight provided for each galaxy (Wake et al. 2017). These weights can be used for correcting back to a volume-limited sample to remove these biases. In this paper, whenever computing any statistical quantity like mean or median for a sample of galaxies, we have used these volume correction factors and referred to the quantity as weighted mean or weighted median. All the histograms shown are also weighted using these weights.

#### 2.1.2. Pipe3D pipeline

All MaNGA galaxies were reduced by Pipe3D (Sánchez et al. 2016a), a fitting pipeline to analyse IFS data (Sánchez et al. 2018). Apart from MaNGA, Pipe3D was also used to process the data from other large IFS surveys such as the Sydney-AAO Multi-object Integral-field spectrograph (SAMi) and Calar Alto Legacy Integral Field Area (CALIFA) surveys (Sánchez et al. 2016a,b, 2012; Croom et al. 2021; Allen et al. 2015). Also, multiple previous works with the MaNGA survey have used Pipe3D outputs. In this subsection, we will briefly discuss Pipe3D and its outputs; a complete description of the software, MaNGA data reduction, and outputs can be found in Sánchez et al. (2016a,b, 2018). To increase the  $S/N$  of the stellar continuum, a binning of the spatial pixels (spaxels) is performed, called the Voronoi tessellation (Cappellari & Copin 2003). This technique aims to get a uniform  $S/N$  per bin by performing adaptive spatial binning of the IFS observations. This is an important requirement for the proper analysis of IFS data. At the beginning, Pipe3D analyses the stellar population and the strong emission lines,

then separately analyses the weak emission lines. Each bin is fitted with a template of simple stellar populations (SSPs) for the stellar population analysis, given the dust attenuation and kinematics. The fitted continuum is subtracted from the full spectrum to get a data cube with only emission lines. Gaussian profiles are used to fit the strong emission lines, and these model emission line profiles are subtracted from the original spectrum to remove the effect of the strong emission lines. A stellar library is used to fit these strong emission-lines-free spectra to determine several properties of the stellar population, like metallicity, age, and star formation history. The error estimates of all these properties are also obtained. The weak spectral line features are then analysed, and parameters are estimated without fitting the Gaussian profile. After the separate analysis of emission lines and stellar continuum is complete, their properties are recovered for each spaxel. The MaNGA Pipe3D value-added catalogue has spatially resolved and integrated properties of galaxies for DR17. We have used some of the integrated properties of the galaxies like  $\lambda_{Re}$ , effective radius, mass-weighted age and metallicity, flux intensity of H $\alpha$  line at  $1 R_e$ , D4000 stellar index at  $1 R_e$ , and inclination (extracted from the NASA Sloan Atlas<sup>1</sup>) We have also used the resolved maps of H $\alpha$  gas velocity, stellar velocity, H $\alpha$  emission line Gaussian flux, and spectral index D4000 in this work. For the visualisation of these 2D maps, we used MaNGA-MARVIN<sup>2</sup> (Cherinka et al. 2019). The resolved maps are provided as 3D data cubes where two axes represent the spaxels and the third axis represents these parameters.

### 2.1.3. SFR and stellar mass

We use the GALEX-SDSS-WISE LEGACY CATALOG (GSWLC-A2; Salim et al. 2016, 2018), hereafter the Salim catalogue, for obtaining stellar mass, SFR and redshift. The Salim catalogue uses the stellar population synthesis technique to model the spectral energy distribution (SED) using ultraviolet, optical, and infrared bands to obtain parameters such as stellar mass and SFR for each galaxy. Input data are taken from the SDSS, Galaxy Evolution Explorer (GALEX) and Wide-Field Infrared Survey Explorer (WISE) all-sky surveys. Several previous studies on star-forming early-type galaxies (e.g. Schawinski et al. 2009; Kaviraj et al. 2009; George & Zingade 2015) have used optical or UV colours as the proxy for star formation activity. Salim (2014) has shown that  $NUV - r$  colour is good at indicating ongoing star formation in galaxies. Nevertheless,

these colour-based identifications of star-forming galaxies do not properly consider the effect of dust attenuation, which varies with the SFR and  $M_*$  of a galaxy (e.g. Salim & Narayanan 2020) and can lead to the wrong identification of a dusty star-forming galaxy as a passive, red galaxy (e.g. Cortese 2012). Determining SFR by modelling the SED is more robust than colour-based techniques to identify star-forming galaxies. The Salim catalogue allows us to select star-forming or quenched galaxies using simple criteria based on the specific star formation rates (sSFR; the ratio of SFR and  $M_*$ ) of galaxies determined from stellar population synthesis modelling. To select star-forming galaxies, we use

$$\text{sSFR}(\log(\text{yr}^{-1})) \geq -10.8 \quad (1)$$

and

$$\text{sSFR}(\log(\text{yr}^{-1})) \leq -11.8 \quad (2)$$

for quenched galaxies following Salim (2014). Objects having  $\text{sSFR}(\log(\text{yr}^{-1}))$  in between  $-10.8$  and  $-11.8$  are called green valley galaxies, which are in transition between the star-forming main sequence and quenched sequence (see, e.g. Bait et al. 2017).

### 2.1.4. Environmental density and the B/T luminosity ratio

We use the local surface density of galaxies as given in Baldry et al. (2006) to measure the environmental density. The density is defined as  $\Sigma_N = N/\pi d_N^2$ , where  $d_N$  is the Nth nearest neighbour distance, and N is the number of galaxies inside the area  $\pi d_N^2$ . This is calculated within the redshift range of  $\pm \Delta z c = 1000$  km/s for galaxies where the spectroscopic redshift is known, or the photometric redshift is known within the 95% confidence limit. The average  $\Sigma_N$  for the fourth and fifth nearest neighbour is the final environmental density following Baldry et al. (2006).

We take the bulge-to-total B/T luminosity ratio from the MaNGA PyMorph (Vikram et al. 2010) DR17 photometric catalogue, which provides photometric parameters of a galaxy from Sérsic and Sérsic+Exponential fits (Fischer et al. 2019; Domínguez Sánchez et al. 2022). It is obtained by fitting the 2D surface brightness profiles of the SDSS-MaNGA DR17 final galaxy sample with a Sérsic+Exponential profile.

### 2.1.5. Morphology

For the morphological classification, we use the MaNGA morphology deep learning DR17 catalogue (hereafter, DL17; Fischer et al. 2019; Domínguez Sánchez et al. 2018; Domínguez Sánchez et al. 2021). This is a deep learning model-based classification of the final SDSS-MaNGA galaxy sample. The conventional neural network algorithm is trained on two catalogues:

<sup>1</sup> <http://nsatlas.org>

<sup>2</sup> <https://dr17.sdss.org/marvin/>

Nair & Abraham (2010), which is a visual morphology classification of the SDSS DR7 (Abazajian et al. 2009) images and Galaxy Zoo 2 (Willett et al. 2013). It claims an accuracy greater than 90% on the deep learning classification. Based on the T-Type, this catalogue separates the late and early-type galaxies better than the Galaxy Zoo MaNGA catalogue. It also gives finer separation between pure ellipticals and S0s. All the deep learning-based classifications were eye-balled for additional reliability, and the catalogue provides a visual classification (VC) number and its reliability flag (VF). Here, we only choose galaxies with certain visual classification (VF = 0). For a clean separation of the galaxies in different morphology classes, Domínguez Sánchez et al. (2021) recommend:

- For LTGs: T-Type > 0 AND P\_LTG  $\geq$  0.5 AND VC = 3
- For S0s: T-Type  $\leq$  0 AND P\_S0 > 0.5 AND P\_LTG < 0.5 AND VC = 2
- For Es: T-Type  $\leq$  0 AND P\_S0  $\leq$  0.5 AND P\_LTG < 0.5 AND VC = 1

P\_LTG is the probability of a galaxy being LTG rather than ETG, and P\_S0 is the probability of a galaxy being S0 rather than a pure elliptical. We follow this prescription to assign a morphology to the galaxies in our sample.

## 2.2. Sample selection

For our analysis, we cross-matched all the catalogues for the mentioned quantities and used appropriate flags mentioned in the catalogues to select only galaxies not flagged in any catalogue. For GSWLC, we used the SED fitting flag (*flag\_sed* = 0) and reduced goodness-of-fit value for the SED fitting ( $\chi_r^2 \geq 5$ ); for DL17 we used the Visual classification flag (*Visual\_Flag* = 0) and for PyMorph we used Sérsic fit flag (*FLAG\_FAILED\_S* = 0) and Sérsic+Exponential fit flag (*FLAG\_FAILED\_SE* = 0). We also checked if all the galaxies in the sample have Pipe3D outputs. As we are interested in nearby galaxies, we put a cut on the redshift of  $z < 0.1$ . All these selection criteria produce 5076 galaxies. We tested for any gross biases produced by these selections. The distribution of stellar mass, sSFR and morphology before and after applying the criteria are very similar. So, we believe these selection cuts did not produce any large biases beyond those already present in the MaNGA selection.

First, we divide our whole sample into three morphological classes: ellipticals (Es), lenticulars (S0s), and spirals (Sps). We used the criteria discussed in subsection

2.1.5 to split the whole sample into these three samples. After this division, we have 1139 Es, 607 S0s, and 3108 Sps. Fig. 1 shows the distribution of the galaxies in sSFR. We can see that spiral galaxies are in the star-forming region, and ellipticals are mostly quenched. In this work, we are interested in elliptical galaxies in the star-forming region. We can also notice that a significant fraction of S0s are also star-forming. Like ellipticals, S0 galaxies are also known to be non-star forming and red (e.g. Martig et al. 2009; Bait et al. 2017; Mishra et al. 2019). So, the study of starforming S0s can also give important insights into the evolution of early-type galaxies (e.g., Rathore et al. 2022; Xu et al. 2021).

We then subdivided our sample based on the sSFR and morphology into three subsamples:

- Star-forming ellipticals (SF-Es; elliptical galaxies with  $\text{sSFR}(\log(\text{yr}^{-1})) \geq -10.8$ )
- Star-forming Spirals (SF-Sps; spiral galaxies with  $\text{sSFR}(\log(\text{yr}^{-1})) \geq -10.8$ )
- Quenched Ellipticals (Q-Es; ellipticals with  $\text{sSFR}(\log(\text{yr}^{-1})) \leq -11.8$ )

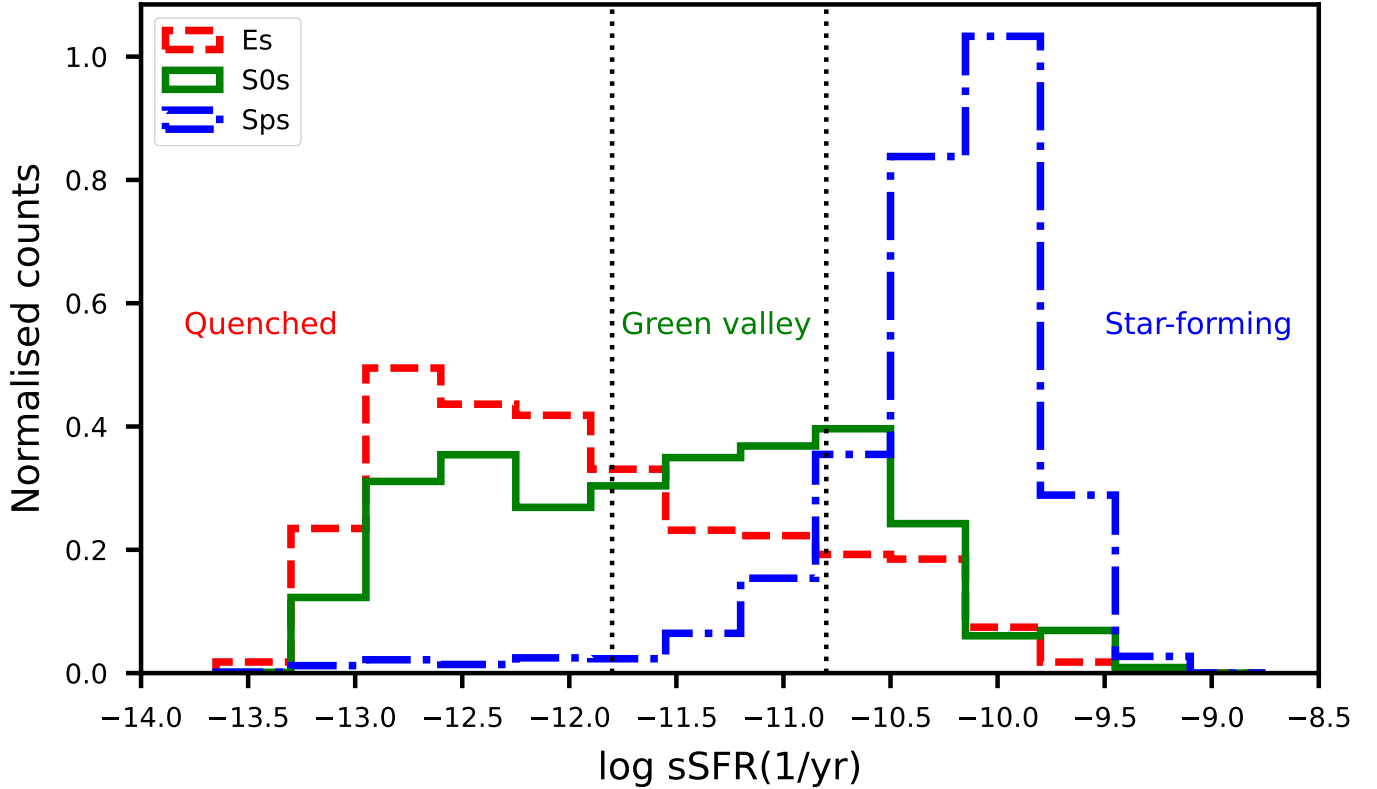

The first is our main sample of interest, the primary sample and the latter two are control samples, which are used to compare different quantities across these samples and draw conclusions from them. The choice of these three samples is motivated by the scientific problem. We are studying the evolution of star-forming ellipticals and how they form stars, unlike their regular counterparts. Also, we aim to investigate if there is any evolutionary connection present between these samples. Stellar mass is a fundamental quantity and plays an essential role in galaxy evolution (Peng et al. 2010). For this reason, we restrict the stellar mass of the control samples (SF-Sps and Q-Es) to the same range as that of the primary sample (SF-Es).

### 2.2.1. Sample of Star-forming ellipticals (SF-Es)

After the basic selection cuts, we use the DL17 criteria and Equation 1 to identify elliptical galaxies that are star-forming. Using these conditions, we obtained 76 star-forming elliptical galaxies.

To identify any morphological misclassification done by the DL17, we carry out a careful visual inspection of the SF-Es in the deeper imaging of Dark Energy Spectroscopic Instrument (DESI) Legacy Survey DR10 (Schlegel et al. 2021) using the Legacy survey Sky Browser<sup>3</sup>. For all the SF-Es, Legacy DR10 images were

<sup>3</sup> <https://www.legacysurvey.org/viewer/>

**Figure 1.** The normalised counts (area under the weighted histogram is one) of galaxies of different morphological types as a function of  $\log(\text{sSFR}(1/\text{yr}))$ . 3099 spiral galaxies are shown by a blue dash-dot line, a green solid line shows 607 S0s, and by a red dashed line, 1139 elliptical galaxies are shown. By dotted black lines ( $\text{sSFR}(\log(\text{yr}^{-1})) = -10.8$  and  $\text{sSFR}(\log(\text{yr}^{-1})) = -11.8$ ), the border between the quenched, green valley and star-forming regions are also shown. Almost all the Sps are in the star-forming region. S0s are equally distributed in quenched and green valley regions and decrease in the star-forming region. Es are mostly quenched, and their population decreases as the sSFR increases but not as rapidly as the population of Sps decreases with decreasing sSFR. The weighted median value of the  $\log(\text{sSFR}(1/\text{yr}))$  for Sps, S0s, and Es are  $-10.17$ ,  $-11.47$ , and  $-12.03$ , respectively. Furthermore, we can also see that a significant fraction of S0s and Es are star-forming. The Es, which are in the star-forming region, form our primary sample.

available. We discarded two galaxies showing spiral features in DR 10 images (see Appendix B), which likely represent a failure of the DL 17 classification. We also looked carefully at edge-on galaxies as their morphological classification is tricky because it is possible to misclassify an edge-on spiral galaxy with a large bulge as an S0 galaxy. This happens because spiral features of spiral galaxies are often invisible at large inclination angles. We did not find any high inclination galaxy in our sample. If the disks of S0s lack bright stars, they tend to be smooth, which makes it challenging to separate S0s from ellipticals, particularly for face-on galaxies. Due to this effect, the sample could contain some S0 galaxies.

Further, we check the  $\text{H}\alpha$  emission line maps and the GALEX data for all the SF-Es. We checked to see if the sSFR value was incorrectly computed due to the presence of a nearby star-forming galaxy. We discarded 14 galaxies without a trace of  $\text{H}\alpha$  emission in their emission maps. These galaxies were also not detected in GALEX.

GALEX detection is a valuable diagnostic because UV luminosity is a measure of the recent star formation activity in the galaxy. We also discarded one galaxy that does not have Pipe3D output. Finally, we have 59 SF-Es left in the sample. The redshift and stellar mass ranges of the 59 SF-Es are respectively  $0.01 < z < 0.08$  and  $8.58 < \log \frac{M_*}{M_\odot} < 11.31$ .

### 2.2.2. Control Sample Of Star-forming Spirals (SF-Sps)

This is our first control sample of star-forming spirals. After applying the basic selection criteria, we select spirals based on the DL17 criteria (for LTG) and use Equation 1 to identify star-forming galaxies. We have also made an additional cut to match the stellar mass range of the SF-Sps with that of the SF-Es. These conditions, taken together, yield 2419 star-forming spiral galaxies. These 2419 galaxies make up our control sample of SF-Sps. Given the large sample size, we did not visually inspect these galaxies. Also, it would be

difficult to misclassify any other morphology to spiral. Considering the claimed accuracy of DL17, there could be at most 10% contamination in this sample.

### 2.2.3. Control Sample Of Quenched ellipticals (Q-Es)

To select ellipticals, we use the DL17 criteria as the primary sample of SF-Es and equation 2 to separate the quenched ellipticals. Further, we again make a selection cut to match the stellar mass range of the sample to be the same as that of the SF-Es. After the basic selection cuts and filtering according to these metrics, we have 684 quenched ellipticals. These 684 galaxies are part of the second control sample of Q-Es. For this sample, we also did not carry out a visual inspection of morphology. Considering the accuracy of DL17 and any other morphological class of galaxies to be truly passive, like ellipticals, there could be contamination from some quenched S0s in this control sample.

## 2.3. Global Properties

Fig. 2 (left panel) shows the stellar mass distribution for SF-Es, SF-Sps, and Q-Es. The star-forming spirals generally have lower stellar mass than the quenched ellipticals. This is consistent with the fact that, on average, star-forming LTGs are less massive, and quiescent ETGs are more massive (Baldry et al. 2004; Conselice 2006; Buitrago et al. 2013; Bait et al. 2017). Surprisingly, the primary sample of SF-Es has a stellar mass distribution similar to SF-Sps. Also, the weighted median of the stellar mass for SF-Es and SF-Sps is the same,  $10^{9.67} M_{\odot}$ , and that for Q-Es is significantly higher at  $10^{10.62} M_{\odot}$ . The population of SF-Es and SF-Sps decreases; on the other hand, the population of Q-Es increases rapidly beyond the stellar mass of  $10^{10} M_{\odot}$ . Most SF-Es have a stellar mass of less than  $10^{10.25} M_{\odot}$ , as seen in most previous studies (Huertas-Company et al. 2010; Kannappan et al. 2009) involving blue or star-forming ETGs. However, with increasing stellar mass, the number of SF-Es does not decrease as rapidly as has been seen with only star-forming S0s (Rathore et al. 2022). This could be because elliptical galaxies are generally more massive than S0s. Here, we can see that the number of lower stellar mass Q-Es is very few. Quenched galaxies tend to be more massive, particularly ellipticals. However, selection bias against Q-Es at lower masses could be present due to limitations of stellar population modelling. These less massive quenched galaxies have very low luminosity, particularly for the bluer bands, resulting in low flux for a given redshift. This makes it difficult or impossible to obtain reliable stellar population estimates for these galaxies from the SPS modelling using UV-Optical-mid-IR band photometry.

Fig. 2 (middle panel) shows the environmental density weighted histogram for SF-Es, SF-Sps, and Q-Es. Here, the average  $\Sigma_N$  for the fourth and fifth nearest neighbour is taken as the environmental density. We can see that the overall distribution of the galaxies with  $\Sigma$  is similar. The number of Q-Es is highest for higher  $\Sigma$  bins, and SF-Sps dominate in the lower  $\Sigma$  bins. This is consistent with quenched ETGs residing in denser regions (Dressler 1980; Bait et al. 2017). The primary sample of SF-Es lies between the SF-Sps and Q-Es. The weighted median values of  $\log \Sigma (\text{Mpc}^{-2})$  for SF-Sps, SF-Es and Q-Es are  $-0.43$ ,  $-0.23$  and  $0.01$ , respectively.

Fig. 2 (right panel) shows the  $\lambda_{Re}$  distribution of galaxies for the three samples. SF-Sps are, on average, fast rotators and dominate the two highest bins in  $\lambda_{Re}$ . Q-Es are slow rotators whose population decreases quickly after  $\lambda_{Re} = 0.6$ . However, the primary sample of SF-Es is a mixture of fast and slow rotators. The weighted median values of  $\lambda_{Re}$  for SF-Sps, SF-Es, and Q-Es are  $0.84$ ,  $0.66$ , and  $0.46$ , respectively.

Actively star-forming galaxies lie on a relatively tight sequence in the SFR stellar mass plane known as the star-forming main sequence (SFMS). Fig. 3 shows the SFMS for our samples. SF-Es are distributed in the SFMS along with the SF-Sps. The weighted median values of the SFR in units of  $M_{\odot} \text{yr}^{-1}$  for the SF-Sps, SF-Es, and Q-Es are  $-0.43$ ,  $-0.66$ , and  $-1.91$ , respectively. In this work, our goal is to understand this population of SF-Es, which lies in the SFMS and not in the quenched region, with the majority of ellipticals.

In the next section, we will describe the results and compare the three samples with each other to gain a clearer insight into the nature of the SF-E population.

## 3. RESULTS

From Pipe3D, we obtain the integral and the resolved properties of individual galaxies. In this section, we present the findings about these properties of our primary sample of SF-Es in comparison with the two control samples. In particular, we compare, in turn, the gas content, size, mass, age, metallicity,  $B/T$ , environmental density, and velocity maps of the galaxies.

### 3.1. Gas content

We have taken the dust-corrected flux intensity of the  $\text{H}\alpha$  line within one  $R_e$  as a proxy for the ionized gas content of the galaxy. HII regions are usually associated with star formation and are detected through their  $\text{H}\alpha$  emission. As shown in Fig. 4 (left panel),  $\text{H}\alpha$  emission from SF-Sps and Q-Es are well separated. This is as expected; the Q-Es have low gas content, while the SF-Sps have high gas content. There are two populations

**Figure 2.** For all the panels, 2419 SF-Sps are shown by a blue dash-dot line, 59 SF-Es are shown by a black solid line, and by a red dashed line, 684 Q-Es are shown. Left panel: The normalized counts of galaxies of the three samples as a function of stellar mass ( $\log(M_*/M_\odot)$ ). The stellar mass distribution of the SF-Es and SF-Sps are similar and have the same weighted median stellar mass of  $10^{9.67} M_\odot$ . Also, on average, SF-Es and SF-Sps are less massive than the Q-Es, which have a weighted median stellar mass of  $10^{10.62} M_\odot$ . Middle panel: The normalized counts of galaxies of the three samples as a function of environmental density ( $\log\Sigma(\text{Mpc}^{-2})$ ). The median values of  $\log\Sigma(\text{Mpc}^{-2})$  for SF-Sps, SF-Es and Q-Es are  $-0.43$ ,  $-0.23$  and  $0.01$ , respectively. The distribution of galaxies across the three samples as a function of environmental density is more or less similar. However, on average, the value of  $\Sigma(\text{Mpc}^{-2})$  increases from SF-Sps to SF-Es and SF-Es to Q-Es. Right panel: The normalized counts of galaxies of the three samples as a function of  $\lambda_{Re}$ . Q-Es are generally slow rotators, and SF-Sps are fast rotators. However, the SF-Es have a mixture of slow and fast rotators. The median value of  $\lambda_{Re}$  for SF-Sps, SF-Es and Q-Es are  $0.84$ ,  $0.66$  and  $0.46$  respectively.

**Figure 3.** Distribution of the galaxies across the three samples in the  $\log(\text{SFR}(M_\odot \text{yr}^{-1}))$  and  $\log(M_*/M_\odot)$  plane (star-forming main sequence). Blue circles show 2436 star-forming spirals, black stars show 59 star-forming ellipticals and 839 quenched ellipticals are shown by red circles. The black dotted lines ( $\log(M_*/M_\odot) = 8.58$  and  $\log(M_*/M_\odot) = 11.31$ ) show the stellar mass range of the primary sample of SF-Es. We matched the stellar mass ranges of the control samples of Q-Es and SF-Sps to the primary sample by selecting galaxies within the two dotted lines. The galaxies outside the lines are discarded from further analysis. This selection results in 2419 SF-Sps and 684 Q-Es, constituting the two final control samples. The weighted median values of  $\log(\text{SFR}(M_\odot \text{yr}^{-1}))$  for SF-Sps, SF-Es and Q-Es are  $-0.43$ ,  $-0.66$  and  $-1.92$ , respectively.

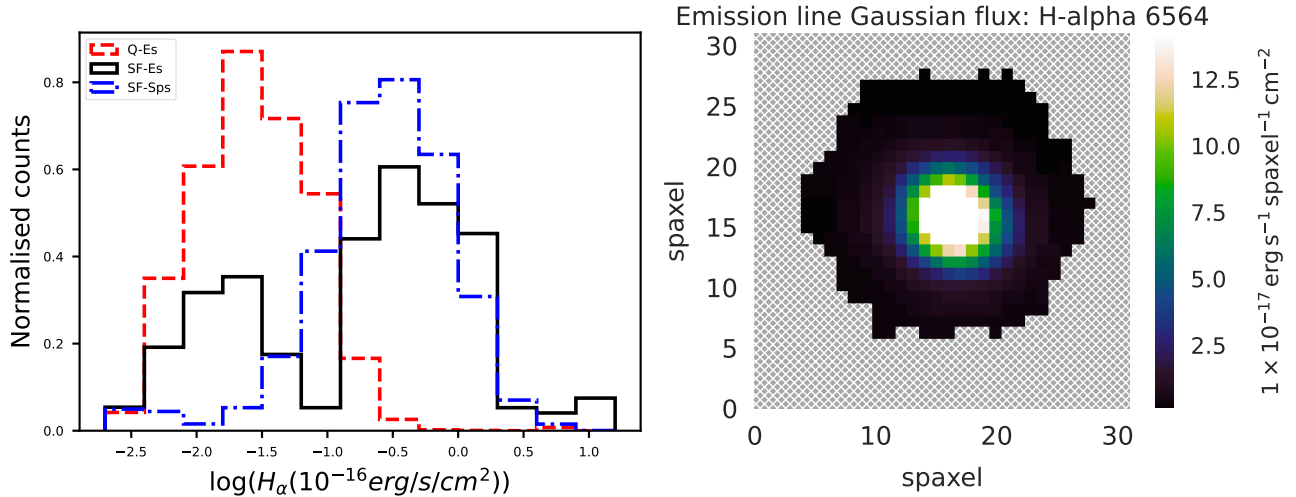

of galaxies in the SF-Es; one has low gas content like the Q-Es, and the other has gas as high as the SF-Sps. From pipe3D, we also have maps of the dust-corrected emission line gas flux of  $\text{H}\alpha$ . In our primary sample, almost all of the SF-Es show an  $\text{H}\alpha$  blob in the centre of the map (see Fig. 4 right panel).

### 3.2. Spectral index: $D4000$

Spectra of early-type galaxies show a red continuum, absorption lines due to the evolved older population of stars and little or weak emission lines because of the lack of (or very weak) star formation. They also show a continuum discontinuity at  $4000 \text{ \AA}$ . This results from the accumulation of absorption lines due to ionised metals in the atmosphere of old stars and the absence of hot, blue stars in the galaxy. So, the strength of the  $4000 \text{ \AA}$  break increases with stellar age (elapsed time since the last star formation activity) and metallicity. The value of this continuum break is measured as the spectral index and calculated as a logarithm of the ratio of integrated flux density redward and blueward of  $4000 \text{ \AA}$ . Moreover, the value of this spectral index can be used to separate old ( $D4000 \sim 1.6 - 2.0$ ) and young ( $D4000 \sim 1.1 - 1.4$ ) stellar populations.

Fig. 5 (upper left panel) shows that the SF-Sps ( $D4000 \sim 1.1 - 1.5$ ) have a young stellar population in contrast to the Q-Es ( $D4000 \sim 1.6 - 1.9$ ), which have an old stellar population. The value of the spectral index  $D4000$  varies between  $1.2 - 1.6$  for the SF-Es. So, our sample of SF-Es has a mixture of young and old stellar populations or a population of intermediate-age stars.

**Figure 4.** We have taken the **dust-corrected**  $H\alpha$  emission line Gaussian flux as the measure of the gas content of the galaxy. This figure (left panel) shows the normalized counts (weighted histogram) of the three samples of galaxies (Q-Es in red, SF-Es in black, and SF-Sps in blue) as a function of  $\log(H\alpha(10^{-16}\text{erg/sec/cm}^2))$ . We can see that the gas content of Q-Es is low compared to the SF-Sps. However, the primary sample of SF-Es shows two distinct populations. In one, the gas content is like SF-Sps; in the other, it is like Q-Es. The weighted median values of  $\log(H\alpha(10^{-16}\text{erg/sec/cm}^2))$  for SF-Sps, SF-Es and Q-Es are  $-0.54$ ,  $-0.57$  and  $-1.57$  respectively. The  $H\alpha$  emission map of one of the SF-Es is shown in the right panel.

We also have the spectral index maps for all of these galaxies. Most of the D4000 maps of SF-Es are like the one shown in Fig. 5 (upper right panel), with a young population of stars in the centre of the galaxy and old stars towards the outer side. We also have some maps showing young stellar populations in the outer regions and older stellar populations in the centre (Fig. 5 lower right panel). Very few of them show a young stellar population distributed all over the galaxy, as shown in Fig. 5 (lower left panel).

### 3.3. Age and metallicity

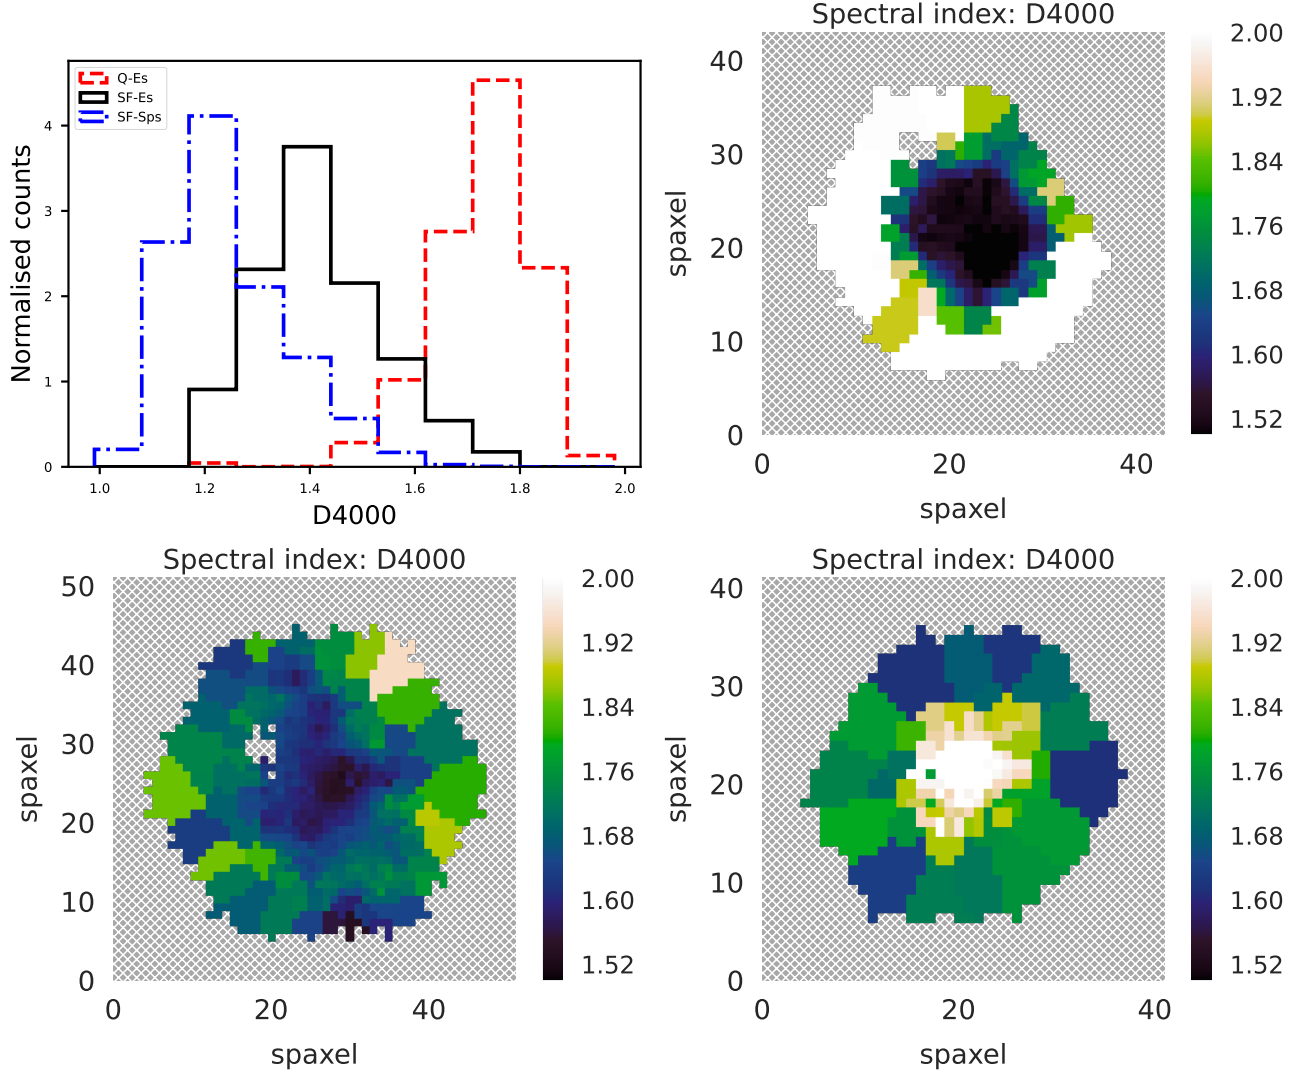

We plotted two elliptical samples (SF-Es and Q-Es) on the age metallicity plane in Fig. 6. Here, age and metallicity are the mass-weighted age and metallicity of the stellar population. As we can see from Fig. 6, both age and metallicity of the stellar population for SF-Es are lower, on average, than the Q-Es. This suggests that, in the recent past, these SF-Es must have acquired metal-poor gas from outside due to some external processes and are forming a new population of stars.

### 3.4. Kinematics

Next, we inspected the kinematic maps of the SF-Es and checked for any disturbances seen in the  $H\alpha$  gas and stellar velocity maps. Any disturbance in these maps could signify interaction activity, such as a merger or gas accretion. We have visually examined all the  $H\alpha$  gas and stellar velocity maps of SF-Es. Based on this visual inspection, we have divided our sample of SF-Es into four categories:

- **Regular:** These are the galaxies where we can see clear rotational structures in both maps, and the rotational axes are aligned. We have 19 galaxies like this.
- **Complex:** Here, either or both maps show disturbance (do not have any clean rotational structure as we see for the regular category) in the system. Some of these objects have gas and stellar rotational axes misaligned. There are 34 galaxies in this class.
- **Counter-rotating:** These objects have a clean rotational structure, but the rotation axes of stars and gas are opposite to each other. There are five objects in this category.
- **No-rotation:** Only one object, a face-on galaxy, where we can not see evidence of rotation in the stellar and gas maps.

In Fig. 7, we have presented one galaxy from each category (regular, complex, counter-rotating, and no-rotation from top to bottom). Here, we want to point out that this classification is based only on visual inspection. Sometimes, due to the small inclination angle of the galaxies, we cannot see the velocity structures correctly. For the SF-Es, we have only three objects with inclination angles less than  $15^\circ$ . So, only these three galaxies can be called face-on galaxies. Among them, the first one is in the no-rotation class (inclination angle  $11.38^\circ$ ), the second one is in the regular class (inclination

**Figure 5.** The upper left panel shows the normalised counts (weighted histogram) of the three samples of galaxies (Q-Es in red, SF-Es in black, and SF-Sps in blue) as a function of the D4000 spectral index, which is a continuum discontinuity at  $4000 \text{ \AA}$ . The value of the D4000 increases with the age of the stellar population and the abundance of metal in a galaxy. We can see that the two control samples of SF-Sps and Q-Es have young and old stellar populations, respectively. However, the primary sample of SF-Es has a mixture of old and young stellar populations. The weighted median values of D4000 for SF-Sps, SF-Es, and Q-Es are 1.23, 1.41, and 1.74, respectively. We have also shown three types of distribution of the resolved D4000 index across the 2D face of three galaxies. Upper right panel: low D4000 at the centre and high at edges, lower right panel: high at the centre and low at the edges, and lower left panel: the low value of D4000 across the galaxy.

angle  $13.70^\circ$ ), and the third one is in the complex class (inclination angle  $14.93^\circ$ ). Hence, we believe that the disturbance seen in the velocity maps for the complex category of SF-Es is not caused by the low inclination angle of these galaxies.

To determine any dependence of the kinematics on the size and mass of the galaxy, we have plotted these objects on the size-mass plane and marked them according to their categories. We can see from Fig. 8 that high-mass SF-Es tend to be more regular than low-mass SF-Es, which tend to be kinematically complex. The reason

for this could be the high rotational inertia of massive galaxies, making it difficult to perturb them kinematically.

Further, using a similar argument as Rathore et al. (2022), we have divided our sample of SF-Es as kinematically settled and unsettled galaxies, where kinematically settled galaxies are the regular ones (19 galaxies), and kinematically unsettled include complex and counter-rotating galaxies ( $34 + 5 = 41$  galaxies). So, of the total sample of SF-Es,  $\sim 2/3$  are kinematically unsettled. Recent interaction and/or mergers are likely

**Figure 6.** Distribution of the two samples of ellipticals SF-Es and Q-Es in the mass-weighted stellar population age-metallicity plane. Both the age and metallicity of the stellar population are, on average, smaller for the SF-Es compared to the Q-Es, suggesting that the SF-Es have acquired metal-poor gas in the recent past. The weighted median values of  $\log(\text{age}(\text{yr}))$  for SF-Es and Q-Es are 9.61 and 9.86 respectively. The weighted median values of  $\log(z/z_\odot)$  for SF-Es and Q-Es are  $-0.35$  and  $-0.04$  respectively. Here, we can see that the histograms and the scatter plot are not exactly in agreement because the histograms are weight-corrected, but the scatter plot is not. We do not correct the scatter plots since the values of the parameters are correct at the individual galaxy level.

to be the reasons behind this (Bendo & Barnes 2000; Di Matteo et al. 2007; Bassett et al. 2017), which might also have supplied the fresh gas needed to form new stars.

### 3.5. Distribution of SF-Es in $B/T - \lambda_{Re}$ plane

To study the structure and kinematics of the SF-Es, we plot them on the  $B/T - \lambda_{Re}$  plane (Fig. 9), where we have taken  $B/T$  as the proxy for structure and  $\lambda_{Re}$  as the proxy for kinematics. Then, we divided them into four classes based on their  $B/T$  and  $\lambda_{Re}$  as follows:

- Class-1 (C1): These objects have  $B/T > 0.7$  and  $\lambda_{Re} < 0.5$ . These are bulge-dominated, slow rotators; we have 8 of them in our primary sample of SF-Es.
- Class-2 (C2): This class of objects have  $B/T > 0.7$  and  $\lambda_{Re} > 0.5$ . In the SF-E sample, we have

16 galaxies in this bulge-dominated, fast rotators category.

- Class-3 (C3): These galaxies have  $B/T < 0.7$ , so they are not totally bulge dominated and  $\lambda_{Re} > 0.5$ , i.e. fast rotators. We have 21 of these SF-Es.
- Class-4 (C4): Like Class-3, these objects are also not entirely bulge-dominated ( $B/T < 0.7$ ), but unlike Class-3, they are slow rotators ( $\lambda_{Re} < 0.5$ ). There are 14 galaxies in this class of SF-Es.

Next, we calculated the weighted mean of the stellar mass and environmental density of these classes, and the following are in decreasing order of stellar mass and environmental density.

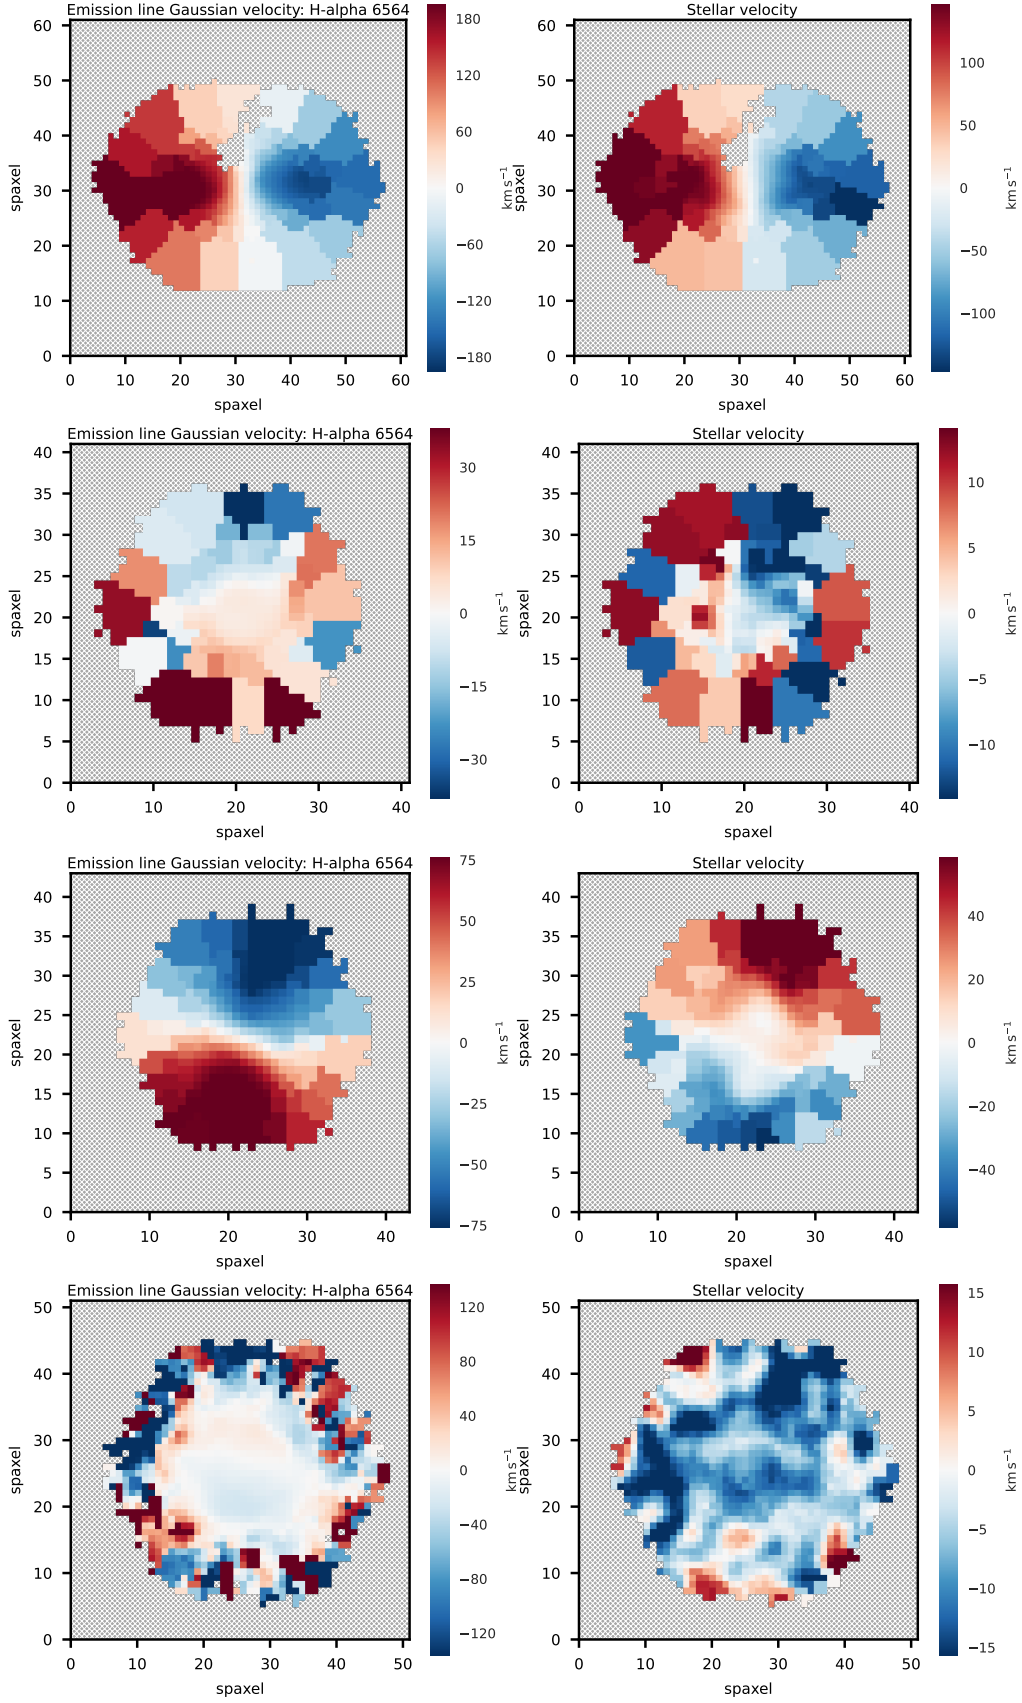

Stellar Mass (weighted mean):  $C1 > C2 > C4 > C3$

Environmental density (weighted mean):  $C1 > C3 > C4 > C2$

So, the stellar mass of the C1 and C2 is the highest, which is expected as they are bulge-dominated ellipticals. The environmental density of C1 is the highest among all the classes, which is also as expected, as they are bulge-dominated, most massive slow rotators. However, the environmental density of C2 is the lowest, which is entirely unexpected. We will discuss these classes individually in Section 4.

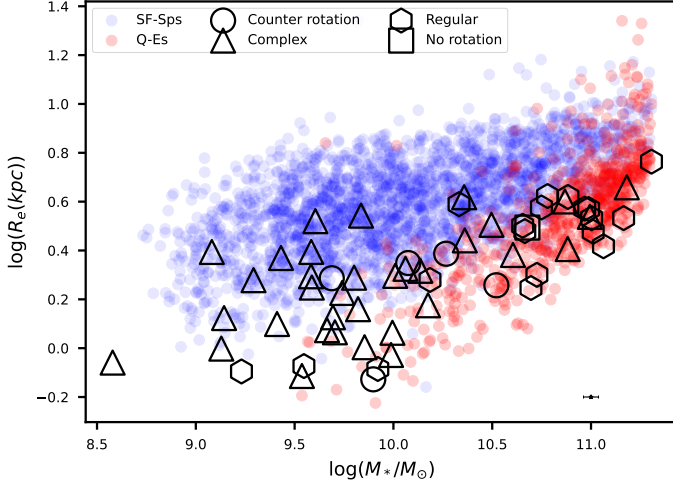

## 4. DISCUSSION

The Hubble sequence (Hubble 1926b) is the morphological classification of galaxies based on visual inspection. It divides galaxies roughly into two broad classes: early-type galaxies (ETGs) and late-type galaxies (LTGs). ETGs include elliptical and lenticular galaxies where Es are dominated by the bulge and supported by high stellar velocity dispersion, and S0s have fast-rotating extended disks. These ETGs are generally red in colour, gas-poor with low or very weak star formation, and are found preferentially in high-density environments. On the contrary, LTGs are spiral galaxies dominated by spiral arms in their extended disk. They are generally blue, gas-rich, star-forming, and found in low-density regions. The Hubble sequence does have its shortcomings. For instance, it considers a simplistic view of the sequential evolution of galaxy morphology from ‘early-type’ to ‘late-type’. Also, we cannot correctly classify galaxies that are in transition between ETG and LTG. Despite these shortcomings, the Hubble sequence is useful for understanding several global galaxy properties and remains widely used in the literature. In this paper, we analyze a class of outliers: elliptical galaxies that form stars at a rate similar to spiral galaxies present in the SFMS despite being morphologically elliptical. These galaxies are extremely uncommon,

**Figure 7.** Example gas (left) and stellar (right) velocity maps of regular, complex, counter-rotating, and no rotation for the four categories (from top to bottom). See the text for a description of each category.

**Figure 8.** Kinematic disturbance trend of the SF-Es on the size-mass plane. SF-Sps are shown in blue circles, and in red circles, Q-Es are shown. SF-Es are marked with different shapes according to their kinematic disturbance categories (see section 3.4). High-mass SF-Es tend to be more regular, and most of the low-mass SF-Es are kinematically unsettled.

**Figure 9.** Distribution of SF-Es (as black stars) and Q-Es (as red circles) in the  $B/T$  and  $\lambda_{Re}$  plane. According to their distribution, we subdivided SF-Es into four classes. Two division criteria ( $B/T = 0.7$  and  $\lambda_{Re} = 0.5$ ) are shown by the blue dotted lines.

but their existence is causing us to question our current understanding of how galaxies evolve. In this paper, we aim to answer some basic questions about this population of star-forming ETGs by studying star-forming ellipticals. The questions we are interested in are:

- What are the global properties of these galaxies relative to the two control samples?

- What drives star formation in these galaxies?
- Where does the gas come from?
- Do some external processes trigger star formation?
- What are the different evolutionary modes for forming stars in these galaxies?
- Can we observationally distinguish between these modes?

In our study, only 5% of ellipticals were SF-Es, consistent with previous studies (Schawinski et al. 2009; Jeong et al. 2021) reporting  $\sim 2 - 7\%$  of the nearby ETGs are star-forming.  $H\alpha$  gas and stellar velocity maps of the  $\sim 67\%$  SF-Es are kinematically unsettled. This includes galaxies with misaligned velocity axes, counter-rotating, and kinematically disturbed velocity maps. Previous surveys like SAURON, SAMI, CALIFA, and ATLAS<sup>3D</sup> have also found that many early-type galaxies (ETGs) show misaligned gas velocity maps with respect to the stellar velocity map (Emsellem et al. 2004; Sarzi et al. 2006; Davis et al. 2011; Barrera-Ballesteros et al. 2015; Bryant et al. 2019). The study by Davis et al. (2011) revealed that approximately 36% of fast rotating ETGs in the ATLAS<sup>3D</sup> have kinematic misalignment. However, this percentage could be higher for star-forming ETGs, as observed in this study. The disturbance in the velocity maps of galaxies indicates external activity like a merger or gas accretion, which can potentially trigger star formation by bringing gas into the system.

Studies of star-forming ETGs have suggested that recent or ongoing interaction with gas-rich neighbouring galaxies is one of the main reasons behind the star formation in passively evolving ETGs. Suppose this process is the primary mechanism behind the formation of star-forming ETGs. In that case, we should expect these galaxies to have higher gas content, lower metallicity, and lower stellar population age than the quiescent ETGs. By studying the  $H\alpha$  emission line flux, we observe that SF-Es have ionized gas content similar to SF-Sps. Wei et al. (2009), using Green Bank Telescope HI data for 27 E/S0s, found that blue sequence E/S0s have atomic gas masses in the range  $10^7 - 10^{10} M_\odot$ , which is substantial and comparable to the atomic gas content of spiral and irregular galaxies with similar stellar mass ranges. Their analysis also suggests that many of these galaxies are capable of significant stellar disk growth.

The mass-weighted stellar population age and metallicity of SF-Es are lower than those of Q-Es, as shown in Fig. 6. The D4000 spectral index of SF-Es ranges from 1.2 to 1.8 (see Fig. 5), implying that these galaxies have a young stellar population mixed with an older

**Figure 10.** The distribution of the four classes (class-1: upper-left, class-2: upper-right, class-3: lower-right, class-4: lower-left) of SF-Es are shown in the size-mass plane. In the background, we have also plotted the control samples of SF-Sps (blue circles) and Q-Es (red circles). The primary sample of SF-Es is shown with black stars. Their kinematic classes are marked with different shapes. The weighted mean trends of the three samples are shown with solid lines.

stellar population or a stellar population with intermediate age. Jeong et al. (2021), inspecting the  $H\beta$ ,  $Mg\ b$ ,  $Fe\ 5270$ , and  $Fe\ 5335$  line strengths, found that star-forming ETGs are more metal-poor than quiescent galaxies.

We divided our primary sample of SF-Es into four classes depending on their position on the  $B/T - \lambda_{Re}$  plane: Class-1, 2, 3, and 4. Here, we will discuss these four classes individually and try to understand their evolutionary history to know the reason for the high SFR in these galaxies. For this, we have plotted them on the size-mass plane and shown their kinematic nature. In the background of the plots, we have also shown our two control samples of SF-Sps and Q-Es. The weighted mean trend of each sample is shown with a solid line (Fig. 10).

The Class-1 objects have  $B/T > 0.7$  (bulge dominated) and  $\lambda_{Re} < 0.5$  (slow rotator). Their stellar masses roughly range from  $10^9$  to  $10^{11} M_\odot$ , i.e. they have high masses. The weighted mean of the envi-

ronmental density is also the highest within these four classes. So, all the properties of this class are like other high-mass ellipticals except for their high SFR. Figure 10 (upper left) shows that out of 8 galaxies in this class, three are kinematically regular, and five are disturbed. So, these rare ellipticals could be regular quenched ellipticals in the past. But recently, their star formation has been rejuvenated, likely due to external processes like mergers or accretion.

Class-2 objects are also bulge-dominated ( $B/T > 0.7$ ) but fast rotators ( $\lambda_{Re} > 0.5$ ). Their mass ranges from  $10^9$  to  $10^{11} M_\odot$ . There are two groups: the high-mass galaxies, which are all kinematically regular, and the relatively lower-mass galaxies, which are all kinematically unsettled (see Fig. 10 upper right). Interestingly, this class of objects has the least weighted mean environmental density. These galaxies could be morphologically transformed spirals. When there is a gas-rich merger, the gas dissipates energy, falls towards the galaxy's centre, and creates a compact starburst region, forming new

stars (Mihos & Hernquist 1994). It has been seen for many fast rotators that their centres are denser than their edges, and they exhibit a steep inner profile (Kormendy et al. 2009). This creates a bulge, and the galaxy slowly changes its morphology from LTG to ETG.

According to Cappellari et al. (2013), there are two separate formation scenarios of the ETGs. The first one is the in-situ star formation, where the galaxy grows via minor gas-rich mergers or gas accretion. Due to the potential well of the galaxy, the gas sinks towards the centre and forms a bulge, which is responsible for the star-formation quenching of the galaxy and disk fading (Cheung et al. 2012; Fang et al. 2013). Because of this process, an LTG morphologically changes to an ETG. The second process predominantly involves dry mergers, leaving the stellar population unchanged (Bezanson et al. 2009; Naab et al. 2009; Hopkins et al. 2010). These two processes are dependent on the environmental density of the galaxies. The first process is dominant in low-density regions, and the second dominates in high-density regions. Also, the ETGs formed via the first process tend to be fast rotators. However, the second method creates slow rotator ETGs. Multiple studies have found that because of the environmental effect in clusters, spirals become passive and transform into S0s (Smith et al. 2005; Boselli & Gavazzi 2006; Moran et al. 2007).

Hence, there is a two-channel build-up process for ETGs. One channel is the bulge growth and quenching route, and here, spiral galaxies are gradually replaced by early-type fast rotators. This channel could form our Class-2 galaxies, where their star formation is still active, and they are in the process of quenching. The second route is the dry merger-growth route, and the mass increase in the slow rotators illustrates it. Our Class-1 objects could result from this second channel, but clearly, their merger growth was not completely dry, and star formation was at least partially rejuvenated during the merger process.

Class-3 objects have  $B/T < 0.7$ , i.e. they are not entirely bulge-dominated and have  $\lambda_{Re} > 0.5$ , so they are fast rotators. Their weighted mean environmental density is also higher next to the class-1 objects. Most of these objects are kinematically unsettled, and their mean trend (see Fig. 10 lower left) is also between SF-Sps and Q-Es. Our interpretation for this class is that these were quenched S0s in the past, and they have rejuvenated their star formation in recent evolutionary history. Almost all the objects here are kinematically complex, indicating recent interactions like merger and/or gas accretion, which increased their gas content fueling the star formation. Some of the galaxies in this class

could be morphologically transformed spirals, which we have discussed above.

According to the mean trend, class-4 is similar to the ellipticals (see Fig. 10 lower right panel). But their  $B/T < 0.7$ , so these objects have a disk and are not entirely bulge-dominated. Almost all of them are kinematically unsettled, and their stellar mass ranges from  $10^{9.5}$  to  $10^{11} M_{\odot}$ . These could be the low redshift counterparts of the red nuggets (Damjanov et al. 2009), which have acquired, over time, a star-forming disc via the ‘Disc-cloaking’ process.

Red nuggets are a class of massive, ultra-compact, quiescent galaxies found in  $z \sim 1 - 2$  but non-existent in the local universe, first reported by Daddi et al. (2005). These galaxies are small in size, but their stellar mass is similar to the giant ellipticals (Longhetti et al. 2007; Toft et al. 2007; Cimatti et al. 2008; Damjanov et al. 2009). Studies (Trujillo et al. 2009; Saulder et al. 2015) based on SDSS show that red nuggets are absent from the local universe. On the other hand, since  $z \sim 1.5$ , the fraction of elliptical galaxies has increased by four times in the last 9 Gyrs ( $z \sim 1.5$ ; Buitrago et al. 2013). The similarity of mass and morphology could connect red nuggets to elliptical galaxies. There is a process called the E-to-E process, through which red nuggets go through a size growth and morphologically change to elliptical galaxies in the present-day universe. In addition, there is a finite possibility that red nuggets have not evolved into quiescent galaxies. They can restart their star formation by accreting gas and stellar clusters around them. It would be a mistake only to assume that red nuggets evolve into ellipticals at present as they are similar in morphology. They can also transform into non-spheroidal systems like S0s and spirals. Graham (2013) suggests an alternative evolutionary mechanism known as ‘Disk-cloaking’ where red nuggets go through minor mergers and accretion (Navarro & Benz 1991; Birnboim & Dekel 2003; Pichon et al. 2011) and experience significant disc-growth, and they are now present in the embedded bulges in S0 and some early-type spiral galaxies. It is possible that this process is the main mechanism responsible for the formation of Class-4 galaxies.

The above results motivate the need to revise the classic Hubble tuning fork diagram (Hubble 1936). A proposed revision of the same, known as the ATLAS-3D comb morphology diagram, was suggested by Cappellari et al. (2011). The shape of this new diagram is not a symmetric fork or a trident but an asymmetric comb. The ETGs are replaced parallel to the LTGs from the handle of the tuning fork. The main features of this revised morphology diagram are as follows:

- A clear distinction between the slow and fast rotators and the link between the S0s and the fast rotators. This takes into account galaxy kinematics, which plays a vital role in galaxy evolution (Capellari 2016). Different IFS and redshift evolution studies independently and consistently show that the evolutionary paths of fast and slow rotators are distinct, one being driven by gas accretion and the other by dry mergers.
- The spirals and S0s are parallel to each other in this revised classification, indicating the close link between spirals and fast rotator ETGs (van den Bergh 1976).
- It incorporates the proposal by Kormendy & Bender (1996) that there should be a link between the S0s and the disk ellipticals.

The last two points imply that galaxies in their lifetime change their morphology. All of our results with the comb morphology diagram, and they both emphasize that many of the essential properties of galaxies, like the gas content and stellar population age, vary along the sequence from ETGs to LTGs and are also shared by the fast and slow rotators populations of ETGs.

## 5. SUMMARY AND CONCLUSIONS

In this work, we have identified and studied a rare class of star-forming ellipticals (SF-Es). Combining data from the DL17 and the Salim catalogues, we identified 59 star-forming elliptical galaxies in the SDSS-MaNGA. Being an IFS survey, MaNGA can provide data on local scales across the two-dimensional face of a galaxy. Using MaNGA Pipe3D and other catalogues, we studied this enigmatic class of SF-Es, both on resolved and global scales. Traditionally, elliptical galaxies are thought to be non or very weakly star-forming. So, a detailed study of the characteristics of these galaxies can give us information about galaxy evolution and how galaxies go through different morphological states and move across the star-forming main sequence.

We study the distribution of the galaxies based on several parameters like stellar mass, SFR, effective radius,  $B/T$ ,  $\lambda_{Re}$ , stellar age, and metallicity across the three samples on the global scale. We also checked the resolved maps of gas velocity, stellar velocity,  $H\alpha$  emission, and D4000 for the 59 SF-Es to get information on the local scale. The following are our main findings:

- The stellar mass distribution shows that SF-Es, on average, have lower stellar mass than Q-Es. The mass distribution of the SF-Es is similar to the SF-Sps. The number of star-forming galaxies amongst

spirals and ellipticals declines roughly after  $10^{10} M_{\odot}$ . Also, SF-Sps and SF-Es are distributed in similar environment-density regions. On the other hand, Q-Es reside in higher-density environments. This is consistent with the idea that mass and environmental quenching play an important role in galaxy evolution.

- $\lambda_{Re}$  for most of the SF-Sps are greater than 0.6, i.e., fast rotators. The number of Q-Es decreases rapidly after 0.6, i.e. Q-Es are mostly slow rotators. Our primary sample of SF-Es contains slow as well as fast rotators. This suggests that using galaxy kinematics is essential for a complete understanding of galaxy evolution processes.
- We considered  $H\alpha$  emission line flux as a measure of the gas content (ionised) of the galaxy. We find that the gas content of SF-Sps is high, and Q-Es have very low gas content. Apart from some galaxies, most SF-Es have  $H\alpha$  emissions similar to SF-Es.  $H\alpha$  maps of SF-Es show that the bulk of the  $H\alpha$  emission comes from the central region of the galaxies.
- D4000 spectral index can separate old (D4000 1.6-2.0) and young (D4000 1.1-1.4) stellar populations in the galaxies. The distribution of spectral index D4000 shows that SF-Sps have the young stellar population, Q-Es have the old stellar population, and the primary sample of SF-Es has a mixture of old and young stellar populations. The D4000 maps of SF-Es show three types of galaxies. The maximum number of galaxies show a young stellar population at the centre and an old population in the outer regions; some show an old population at the centre and a young population outside, and very few show a young population of stars distributed all over the galaxy.
- When two samples of ellipticals star-forming and quenched were plotted in the mass-weighted stellar population age-metallicity plane, it shows that the SF-Es have systematically lower metallicity and age of the stellar population compared to the Q-Es. So SF-Es seem to have acquired metal-poor gas in the recent past.
- The complex velocity structure of the velocity maps indicates disturbances in the system, possibly because of some external or internal interactions in the galaxies. 2/3 ( $\sim 67\%$ ) of the SF-Es are kinematically unsettled, implying recent interactions and mergers. Minor mergers could be a

potent driver of rejuvenation in elliptical galaxies by bringing metal-poor gas into the galaxy.

- We then subdivided our sample of SF-Es into four classes based on their  $B/T$  and  $\lambda_{Re}$  values, and every class of galaxies has its own evolutionary history and mode of formation. Class-1 objects are bulge-dominated ( $B/T > 0.7$ ), slow rotators ( $\lambda_{Re} < 0.5$ ). These galaxies are classical rejuvenated ellipticals. Class-2 objects are also bulge-dominated ( $B/T > 0.7$ ) but fast rotators ( $\lambda_{Re} > 0.5$ ). These could be morphologically transformed spiral galaxies. Class-3 galaxies are not fully bulge-dominated ( $B/T < 0.7$ ), fast rotators ( $\lambda_{Re} > 0.5$ ). These could be rejuvenated S0s, fading spirals, or a mixture of both. Class-4 galaxies are also not fully bulge-dominated ( $B/T < 0.7$ ) but slow rotators ( $\lambda_{Re} < 0.5$ ). These objects could be similar to red nuggets, which have acquired a star-forming disc.

All the above findings imply that these intriguing and rare galaxies do not belong to a homogeneous class of objects. There could be different underlying processes responsible for the formation of SF-Es. Also, our results support the comb morphology diagram, which is a revision of the classical Hubble tuning fork diagram. The comb morphology diagram emphasises three points: parallelism between spirals and S0s, the link between S0s and ellipticals and the distinction between fast and slow rotators.

Further in-depth studies for larger samples of galaxies, preferably volume-limited, spanning across stellar mass, morphology, and redshift, will be needed to draw a complete picture of this elusive class of star-forming ellipticals. HI and molecular gas observations will provide complementary data in these types of studies. Such observations can provide accurate estimates of the gas content and insights into the efficiency and time scale of star formation in these systems.

## ACKNOWLEDGMENTS

We thank the anonymous referee whose comments and suggestions have improved both the content and presentation of this paper. This research made use of Astropy,<sup>4</sup> a community-developed core Python package for Astronomy (Astropy Collaboration et al. 2013, 2018, 2022).

Funding for the Sloan Digital Sky Survey IV has been provided by the Alfred P. Sloan Foundation, the U.S. Department of Energy Office of Science, and the Participating Institutions. SDSS-IV acknowledges support and resources from the Center for High-Performance Computing at the University of Utah. The SDSS website is [www.sdss.org](http://www.sdss.org). SDSS-IV is managed by the Astrophysical Research Consortium for the Participating Institutions of the SDSS Collaboration, including the Brazilian Participation Group, the Carnegie Institution for Science, Carnegie Mellon University, Center for Astrophysics — Harvard & Smithsonian, the Chilean Participation Group, the French Participation Group, Instituto de Astrofísica de Canarias, The Johns Hopkins University, Kavli Institute for the Physics and Mathematics of the Universe (IPMU) / University of Tokyo, the Korean Participation Group, Lawrence Berkeley National Laboratory, Leibniz Institut für Astrophysik Potsdam (AIP), Max-Planck-Institut für Astronomie (MPIA Heidelberg), Max-Planck-Institut für Astrophysik (MPA Garching), Max-Planck-Institut für Extraterrestrische Physik (MPE), National Astronomical Observatories of China, New Mexico State University, New York University, University of Notre Dame, Observatório Nacional / MCTI, The Ohio State University, Pennsylvania State University, Shanghai Astronomical Observatory, United Kingdom Participation Group, Universidad Nacional Autónoma de México, University of Arizona, University of Colorado Boulder, The University of Oxford, University of Portsmouth, University of Utah, University of Virginia, University of Washington, University of Wisconsin, Vanderbilt University, and Yale University.

The Legacy Surveys consist of three individual and complementary projects: the Dark Energy Camera Legacy Survey (DECaLS; Proposal ID #2014B-0404; PIs: David Schlegel and Arjun Dey), the Beijing-Arizona Sky Survey (BASS; NOAO Prop. ID #2015A-0801; PIs: Zhou Xu and Xiaohui Fan), and the Mayall z-band Legacy Survey (MzLS; Prop. ID #2016A-0453; PI: Arjun Dey). DECaLS, BASS and MzLS together include data obtained, respectively, at the Blanco telescope, Cerro Tololo Inter-American Observatory, NSF’s NOIRLab; the Bok telescope, Steward Observatory, University of Arizona; and the Mayall telescope, Kitt Peak National Observatory, NOIRLab. The Legacy Surveys project is honoured to be permitted to conduct astronomical research on Iolkam Du’ag (Kitt Peak), a mountain with particular significance to the Tohono O’odham Nation.

NOIRLab is operated by the Association of Universities for Research in Astronomy (AURA) under a cooperative agreement with the National Science Foundation.

<sup>4</sup> <http://www.astropy.org>

This project used data obtained with the Dark Energy Camera (DECam), which was constructed by the Dark Energy Survey (DES) collaboration. Funding for the DES Projects has been provided by the U.S. Department of Energy, the U.S. National Science Foundation, the Ministry of Science and Education of Spain, the Science and Technology Facilities Council of the United Kingdom, the Higher Education Funding Council for England, the National Center for Supercomputing Applications at the University of Illinois at Urbana-Champaign, the Kavli Institute of Cosmological Physics at the University of Chicago, Center for Cosmology and Astro-Particle Physics at the Ohio State University, the Mitchell Institute for Fundamental Physics and Astronomy at Texas A&M University, Financiadora de Estudos e Projetos, Fundacao Carlos Chagas Filho de Amparo, Financiadora de Estudos e Projetos, Fundacao Carlos Chagas Filho de Amparo a Pesquisa do Estado do Rio de Janeiro, Conselho Nacional de Desenvolvimento Cientifico e Tecnologico and the Ministerio da Ciencia, Tecnologia e Inovacao, the Deutsche Forschungsgemeinschaft and the Collaborating Institutions in the Dark Energy Survey. The Collaborating Institutions are Argonne National Laboratory, the University of California at Santa Cruz, the University of Cambridge, Centro de Investigaciones Energeticas, Medioambientales y Tecnologicas-Madrid, the University of Chicago, University College London, the DES-Brazil Consortium, the University of Edinburgh, the Eidgenossische Technische Hochschule (ETH) Zurich, Fermi National Accelerator Laboratory, the University of Illinois at Urbana-Champaign, the Institut de Ciencies de l’Espai (IEEC/CSIC), the Institut de Fisica d’Altes Energies, Lawrence Berkeley National Laboratory, the Ludwig Maximilians Universitat Munchen and the associated Excellence Cluster Universe, the University of Michigan, NSF’s NOIRLab, the University of Nottingham, the Ohio State University, the University of Pennsylvania, the University of Portsmouth, SLAC National Accelerator Laboratory, Stanford University, the University of Sussex, and Texas A&M University.

BASS is a key project of the Telescope Access Program (TAP), which has been funded by the National Astronomical Observatories of China, the Chinese Academy of Sciences (the Strategic Priority Research Program “The Emergence of Cosmological Structures” Grant # XDB09000000), and the Special Fund for Astronomy from the Ministry of Finance. The BASS is also supported by the External Cooperation Program of the Chinese Academy of Sciences (Grant # 114A11KYSB20160057), and the Chinese National Natural Science Foundation (Grant # 11433005). The Legacy Survey team makes use of data products from the Near-Earth Object Wide-field Infrared Survey Explorer (NEOWISE), which is a project of the Jet Propulsion Laboratory/California Institute of Technology. NEOWISE is funded by the National Aeronautics and Space Administration. The Legacy Surveys imaging of the DESI footprint is supported by the Director, Office of Science, Office of High Energy Physics of the U.S. Department of Energy under Contract No. DE-AC02-05CH1123, by the National Energy Research Scientific Computing Center, a DOE Office of Science User Facility under the same contract, and by the U.S. National Science Foundation, Division of Astronomical Sciences under Contract No. AST-0950945 to NOAO.

## DATA AVAILABILITY

All the data used in this study are publicly available. The catalogue of star-forming ellipticals (SF-Es), star-forming spirals (SF-Sps) and quenched ellipticals (Q-Es) that were constructed are available in the online version of this paper as supplementary material.

*Facilities:* SDSS-MaNGA

*Software:* TOPCAT (Taylor 2005), astropy (Astropy Collaboration et al. 2013, 2018, 2022)
