The Nonlinear Sigma Model With Distributed Adaptive Mesh Refinement

Steven L. Liebling

Southampton College, Long Island University, Southampton, NY 11968

(Dated: November 1, 2018)

An adaptive mesh refinement (AMR) scheme is implemented in a distributed environment using Message Passing Interface (MPI) to find solutions to the nonlinear sigma model. Previous work studied behavior similar to black hole critical phenomena at the threshold for singularity formation in this flat space model. This work is a follow-up describing extensions to distribute the grid hierarchy and presenting tests showing the correctness of the model.

The problem of modeling collisions of two black holes in general situations poses a number of very difficult problems. One among these is finding enough computational resources to adequately resolve the physics in a reasonable amount of time. Adaptive mesh refinement (AMR), whereby fine grids are added where and when needed, has proved successful at enabling a tremendous dynamic range in resolution. However, even with the efficiencies provided by AMR, single machines often fail to provide adequate memory or speed. A logical next step is then to distribute the AMR problem across a cluster of processors.

Perhaps the most well known use of AMR in relativity is Choptuik's implementation of gravitational collapse in spherical symmetry [1]. Studying the threshold of black hole formation required a large range in resolution to resolve the unique behavior he discovered in so called black hole critical phenomena. Other efforts with AMR include modeling a single black hole [2, 3], perturbations of a black hole [4], binary black hole initial data [5], gravitational waves [6], various cosmological models [7], a scalar field using characteristic coordinates [8], fixed mesh refinement [9], orbiting black holes [10], and axisymmetric gravitational collapse [11, 12].

I describe an implementation of distributed AMR in a model problem much simpler than gravitational collapse, but which nevertheless poses an interesting computational problem. In particular, I find solutions to the nonlinear sigma model using a parallel implementation of AMR as a step towards extending the same computational infrastructure to solve the gravitational field equations.

Previously [13], solutions to this model were found using serial AMR (a single machine) which showed a type of threshold behavior similar to black hole critical behavior [1]. Families of initial data parameterized by some parameter p demonstrated two types of behavior. For small p, energy dispersed to infinity (the so-called *subcritical* regime). For large p, evolutions suggest that a singularity forms at finite time (*super-critical*). Tuning between these two states (dispersal and singularity formation), one finds the *critical* regime $p \approx p^*$ in which solutions approach a unique solution independent of the family with which one begins. This solution is the *critical solution* and demonstrates self-similarity.

This paper serves as a follow-up to [13]. Presented first

are the model equations. I then discuss details about the implementation of the model and the distributed AMR algorithm. Tests of the numerical code follow along with a discussion of the parallel performance of the code.

The model: The nonlinear sigma model provides an interesting toy model with which to explore distributed AMR. Choosing a generalized hedgehog ansatz [13], the dynamics of the model reduce to a single equation of motion for a scalar field $\chi(x, y, z, t)$

$$\ddot{\chi} = \chi_{,xx} + \chi_{,yy} + \chi_{,zz} - \frac{\sin 2\chi}{r^2},\tag{1}$$

where commas indicate partial differentiation with respect to subscripted coordinates, an overdot denotes $\partial/\partial t$, and $r \equiv \sqrt{x^2 + y^2 + z^2}$. The equation of motion (1) implies the regularity condition $\chi(0,0,0,t) = 0$ which is enforced by the evolution procedure. The energy density associated with this system is given by

$$\rho = \frac{1}{2} \left[\left(\dot{\chi} \right)^2 + \left(\chi_{,x} \right)^2 + \left(\chi_{,y} \right)^2 + \left(\chi_{,z} \right)^2 \right] + \frac{\sin^2 \chi}{r^2}, \quad (2)$$

while the angular momentum densities are given by [14]

$$M^{\mu\nu} = \int d^3x \left(T^{0\mu} x^{\nu} - T^{0\nu} x^{\mu} \right), \qquad (3)$$

where the z-component of the angular momentum, for example, is

$$J_{z} = \int d^{3}x \ M^{xy} = \int d^{3}x \ \dot{\chi} \left(y\chi_{,x} - x\chi_{,y} \right).$$
(4)

Initial data for χ at t = 0 is set to a generalized Gaussian pulse, and then evolved using the equation of motion (1) with second-order finite differences in an iterative Crank-Nicholson scheme.

Implementation: Certain solutions of this model require a tremendous dynamic range achievable only with AMR. The method implemented here follows that of Berger and Oliger [15] though with certain simplifications. The general strategy is that during the course of an evolution, the dynamics are monitored such that when more resolution is needed, finer sub-grids are created in the regions which demand it. Concurrently, when the dynamics no longer dictate the existence of fine grids, they are removed. The description which follows is intended only to present the choices and simplifications specific to this implementation and therefore assumes some familiarity with the general algorithm as described in [15].

Consider a grid with uniform grid spacing $h = \Delta x = \Delta y = \Delta z$. Some refinement criterion is chosen to determine which points on the grid require increased resolution, a process called *flagging*. In this model, points for which the energy density obeys $h^2 \rho > \epsilon$, for some threshold value ϵ , are flagged. This condition compares the size of the squared derivatives, ρ , to the resolution squared, $1/h^2$. Other refinement criteria are widely used including estimates of truncation error, but this choice works well for this model.

Once points are flagged, bounding boxes are established by *clustering* those points into rectangular regions where sub-grids of finer resolution will be created. One simplification assumed in this code is that grids are completely nested within their parent which means that grids have unique parents. This restricts the types of clustering allowable, and here a very simple method is used. A bounding box is found for each disconnected set of flagged points. In addition, a buffer region around all flagged points is included. Points within two grid points of a flagged point are themselves flagged. This buffering helps ensure that moving features needing refinement stay within refined regions at least until the next refinement occurs.

Each grid's resolution is an integral multiple of its parent's, called the *refinement factor*. This implementation requires this factor to be even. Newly created sub-grids are first initialized by linear interpolation in space from their parent. Then information from other grids at the same resolution (*siblings*), including those destined for removal, is used, where available, to initialize the grid. Around the boundaries of regions initialized from siblings, points are linear interpolated in space to smooth out irregularities between the data from the parent and from its siblings.

Advancement in time of a sub-grid follows that of coarser grids. In particular, once its parent takes a time step, boundary values for advanced time steps of the subgrid are interpolated in time and space from the parent. The sub-grid then takes a number of steps equal to the refinement factor until it is time aligned with its parent. At that point, the parent grid is injected via half-weighted restriction from values in the sub-grid.

The grid hierarchy can be considered as the union of levels, where a level consists of all grids at a given resolution. Thus the coarse grid constitutes Level 0, all its immediate children fill out Level 1, its grandchildren form Level 2, and so on. An example of a grid hierarchy and how it is stored is shown in Fig. 5.

A number of strategies exist for distributing an AMR code. Hoping to achieve a reasonably simple implementation of what is inherently complex, the method adopted here is to distribute grids in their entirety to different processors. An alternative would be to take a piece of every grid and place it on the various processors. Here, the different processors "own" different grids and are responsible for their time stepping and for any output to data files. However, all processors maintain their own copy of the grid hierarchy (as shown in Fig. 5) but do not store the fields that live on grids owned by others. Such a scheme necessitates that various inter-grid communication traverses the network, except in the cases where the involved grids are owned by the same processor.

One advantage to this strategy is that much of the code written for a single processor (the *serial code*) carries over directly. In fact, much of the inter-grid routines carry over with only minimal changes. For example, to provide boundary conditions for an advanced time step of a sub-grid, boundary values are interpolated in time from a parent grid. In the serial version, such values could be calculated in place, whereas in the distributed version coarse grid values are interpolated in time on the coarse grid's processor, and are then sent to the fine grid's processor where the values are interpolated in space. Such a scheme minimizes the amount data needed to be transmitted and also allows the same routines to be used for the serial version just without transmitting the data.

These grids need to be stepped in coordination so that when boundary values are needed by a child grid, the parent is advanced to the correct time before those values are computed. This coordination is provided by having a *master* processor which owns the coarse grid with all other processors entering *slave* mode. In this mode, they continually loop responding to commands passed from other processors over the network.

In the serial version, for each coarse grid time step, appropriate actions are taken on entire levels. A similar approach works for the distributed code. For example, say Level 3 has been advanced, and it is now time to update the boundary values on all grids on Level 4. Then the master processor loops over all grids on Level 4 owned by other processors and sends a command to those owner processors to update the boundaries of the appropriate grids. It then, proceeds by updating the boundary values of all Level 4 grids it owns. Finally, it enters slave mode in which it listens in case it owns grids which must provide such boundary values. Allowing each processor more autonomy would likely increase scaling performance but would add to the complexity.

Distribution of the computational problem achieves two goals. The first is that the computation is sped up with respect to running a single processor. The second is that the memory available increases with the number of nodes. Ideally, both these scale close to linearly with the number of nodes. In the case of speed, optimal scaling can only be achieved if the processors are kept busy, else it is possible for no speed increase to occur. This problem is called *load balancing* and merits quite a bit of literature with a variety of schemes.

Here, such concerns are postponed for later study, and instead a nearly trivial scheme is implemented. That scheme involves maintaining a table of the workload on each processor. Every subgrid of the coarse grid is assigned to the least loaded processor. For other subgrids,

5 4 Q(t) 3 2 1 0 2 $\ln |\Delta J_z(t)|$ 4 6 2 $\ln |\Delta E(t)|$ E(0) 4 6 2 8 0 6 4 t

FIG. 1: Tests of a typical unigrid evolution with numbers of points: $(32 + 1)^3$ (solid, black), $(64 + 1)^3$ (dot, blue), $(128 + 1)^3$ (short dash, green), and $(256 + 1)^3$ (long dash, yellow). The **top frame** shows the convergence factor Q(t) as in Eq. 5. For low resolution, convergence is poor, but as resolution increases, the convergence rapidly improves, approaching the expected value 4. The **middle frame** shows the loss of the z-component of the angular momentum as a function of time, where $\Delta J_z(t) \equiv J_z(t) - J_z(0)$. As the resolution increases, the loss decreases as would be expected for a convergent code. The **bottom frame** shows the loss of energy as a function of time. As with the angular momentum, the loss converges toward zero. The dimensionless ratio of the angular momentum to the energy squared is $J/E^2 = 0.0072$.

they are assigned to the process which owns their parents unless there is a processor with no workload. A number of inter-grid operations occur between a parent and a child, and hence the scheme favors putting children on the same processor as their parent.

The distributed code is sufficiently similar to the serial version that only the distributed version is maintained. Of course, it can still be run on a single processor, and the incumbent overhead is minimal.

Another benefit to such a code is that it can accomplish domain decomposition in which the computational domain can be partitioned into equal chunks and processed on different processors. Decomposition enables one to take advantage of distributed resources without adaptive mesh refinement, and is carried out be defining the zeroth level to consist of multiple grids which cover the entire domain. A future goal is to be able adapt upon this decomposed coarse grid.

FIG. 2: Tests of an AMR evolution. The initial data is equivalent to that shown in Fig. 1. The three runs use identical adaptive hierarchies modulo a factor of 2 in resolution. The **top frame** shows the convergence factors for the respective coarse grids (solid, black), the Level 1 grids (dot, blue), and the Level 2 grids (short dash, green) for the times that they exist. The **middle** and **bottom frames** show the change in angular momentum and energy, respectively computed as an integral over the entire grid hierarchies. The data correspond to runs with coarse grids of resolution: $(32 + 1)^3$ (solid, black), $(64 + 1)^3$ (dot, blue), and $(128 + 1)^3$ (short dash, green).

Tests: A very strong test of the code was presented in the first paper [13] in which the obtained critical solution was compared with results from a 1D code [16]. These solutions span an extraordinary range of resolutions, and that they agree is strong evidence that the codes model the same system.

More traditional tests also provide evidence for the fidelity of the evolutions to the proper equations. In particular, one can examine the behavior of numerical solutions as resolution is increased. Representing a numerical solution at some resolution h by $\tilde{\chi}_h$, we can define a convergence factor

$$Q(t) = \frac{|\tilde{\chi}_{4h} - \tilde{\chi}_{2h}|_2}{|\tilde{\chi}_{2h} - \tilde{\chi}_h|_2}$$
(5)

in terms of solutions found for three successive resolutions h, 2h, and 4h. If the solutions converge to a unique solution, this factor will be greater than unity, and for second-order convergence one expects a factor of four.

In a similar fashion, one expects numerical solutions to maintain approximately conserved quantities. Monitoring changes in the computed energy and angular momentum, one expects these changes to converge to zero as resolution increases. As shown in Fig. 1, for typical initial data, the convergence factor approaches four while changes in energy and angular momentum about the zaxis converge to zero.

A similar test is presented in Fig. 2 in which the same initial data was tested using AMR. Here, with a coarse grid of $(33 + 1)^3$ points, an evolution allowing for three levels of refinement is run which outputs a history of sub-grids created. The resolution of the coarse grid is doubled and run again with refinements dictated by the refinement history recorded in the previous run. In this fashion, adaptive runs can be duplicated with the only change being a multiple of the base resolution. These results indicate convergence and can be compared to the results in Fig. 1.

The code has also shown to give the same results to within machine precision when run on a varying number of processors.

Performance: As already mentioned, the efforts described here are aimed at achieving better performance by utilizing multiple processors, but are not expected to achieve optimal performance. With that said, it makes sense to examine the performance as a function of the number of processors.

With the design calling for entire grids to be placed on processors (as opposed to breaking all grids into smaller grids), there are two regimes of expected performance. If each Level consists of a single grid, then the grids are nested within each other and the grid hierarchy is completely *vertical*. In this regime, generally little speedup is expected. The reason is that the finest grid will usually require the most work, and hence all other processors will generally have to wait for the finest grid to complete before proceeding. Because the other grids take much less work than the finest grid, if one were to run such an evolution on a single processor, it would take about as long as on many.

The other regime is where there are many grids at the same resolution with about the same number of points. For this case, the grid hierarchy is spread *horizontally*. For such a system, the processors can truly act in parallel, and a significant speedup is expected.

As a first test, such a scenario (see Fig. 3) is implemented by forcing the code to create some number of equal sized grids as children of the coarsest grid. We can define a speedup factor S in terms of the time T_n it takes for the code to complete on n dual processor nodes as

$$S = \frac{T_1}{T_n}.$$
 (6)

 T_1 is the time taken on one dual processor node (*e.g.* two processors).

These speedup factors are shown in Fig. 4, for two variations. The first is that these subgrids remain fixed

FIG. 3: 2D slice of initial data with 125 sub-grids. The data shows five equal-sized sub-grids in each dimension. The situation for two, three, and four sub-grids per side (8, 27, 64 total sub-grids) is similar. For so called "static" runs, no re-refinement was done, and for "moving" the sub-grids were successively moved one grid point with each refinement.

while the second has the subgrids moved a single grid point every few time steps. The latter variation is to simulate grids which move and their incumbent network overhead. The figure shows that the execution time is sped up but the improvement generally saturates beginning when the number of processors exceeds half of the total number of grids. In other words, good performance is predicated on having many grids per processor.

A less contrived test would simply compare run times on various numbers of processors. However, for this model, the essential dynamics consist of central collapse, and hence a typical, well resolved evolution would contain a number of grids largely nested within each other in the so-called vertical regime. As such, significant speedup is not expected, but there is benefit in that distributing the problem provides gains in memory storage.

Conclusion: These results indicate the validity of the implementation of the nonlinear sigma model, and in particular support the assertion that, within the hedgehog ansatz but away from spherical symmetry, the critical solution between dispersion and singularity formation is the same as that found under the assumption of spherical symmetry [16].

This work serves as an initial step toward modeling general gravitational collapse with distributed adaptive mesh refinement. Much work remains, including the implementation of more sophisticated clustering and load balancing.

FIG. 4: Scaling performance on an Itanium cluster (titan.ncsa.uiuc.edu at NCSA). Pairs of data are shown, one for so-called "static" and one for "moving" runs of a certain number of sub-grids. In general, the better performing of the pair (the one on top) is the "static." The various cases consist of: plus signs (+) for the 8 sub-grid case; crosses (\times) for the 27 sub-grid case; asterisks (*) for the 64 sub-grid case; and boxes (\Box) for the 125 sub-grid case. The dashed line indicates ideal, linear scale-up. The figure indicates significant speed-up as long as an average of at least two grids exist per process (in other words, the number of nodes is less than a quarter the number of sub-grids).

FIG. 5: Diagram detailing the structure of the stored grid hierarchy. Shown is a simple example of a three-level tree with grids represented as rectangles. Each grid has a unique grid number and also stores its *parent*, its next *sibling*, and a single *child*. In instances in which a sibling/child/parent does not exist, a null pointer is used. The hierarchy also stores the process id which "owns" the grid (and therefore stores the associated fields defined on that grid). Levels, which consist of all (sub-)grids at a given resolution are represented in the diagram as ellipses. Levels store only the beginning grid number in the hierarchy, with subsequent grids obtained by traversing the sibling pointers until a null pointer is reached.
