#### Abstract

The surface of a three dimensional topological insulator (TI) hosts surface states whose properties are determined by a Dirac-like equation. The electronic system on the surface of TI nanowires with polygonal cross-sectional shape adopts the corresponding polygonal shape. In a constant transverse magnetic field, such an electronic system exhibits rich properties as different facets of the polygon experience different values of the magnetic field due to the changing magnetic field projection between facets. We investigate the energy spectrum and transport properties of nanowires where we consider three different polygonal shapes, all showing distinct properties visible in the energy spectrum and transport properties. Here we propose that the wire conductance can be used to differentiate between cross-sectional shapes of the nanowire by rotating the magnetic field around the wire. Distinguishing between the different shapes also works in the presence of impurities as long as conductance steps are discernible, thus revealing the sub-band structure.

## I. INTRODUCTION

Properties of charged particles moving in two dimensions (2D) in a constant magnetic field are described by Landau levels, and this holds both for particles governed by the Schrödinger equation and the Dirac equation. The corresponding energy spectra do not depend on the direction of the magnetic field, only on the magnitude of the perpendicular projection of the field, in the absence of Zeeman coupling. In systems where the magnetic field projection normal to the surface changes sign, interesting physics can occur, e.g., the presence of states with trajectories along the spatial lines of zero normal magnetic field. Such so-called snake states have been studied in nanostructures, first for semiconductors in the integer quantum Hall regime ${ }^{1-3}$, and later in graphene ${ }^{\sqrt{4}}$.

Snake states can also occur in a constant magnetic field if the relative orientation of the electronic system changes with respect to the direction of the field, which is the situation for electrons localized on the surface of a nanowire ${ }^{5-10}$. For semiconducting nanowires the electronic system may be engineered to follow the surface using Fermi level pinning ${ }^{[11}$, or a core-shell heterostructure with an insulating core and a conducting shell ${ }^{12-14}$. An interesting feature of the semiconductor nanowires is that the cross section typically assumes a polygonal shape, e.g., hexagonal. Notably, if the electrons are constrained to such a narrow shell, the lowest energy states become localized at the corners of the polygonal cross section for Schrödinger-like systems ${ }^{[15-17]}$, while in a magnetic field the electronic states show properties that can change from Landau levels to snaking states depending on which facet the electrons are located ${ }^{[18]}$. Such nanowires can be considered tubular conductors, with a prismatic geometry, and their electrical conductance in the presence of a transverse magnetic field is expected to depend on the relative angles between the magnetic field and the facets of the nanowire surface ${ }^{19}$. However, to the best of our knowledge, this kind of anisotropic conductivity has not been reported in experimental studies.

FIG. 1: A nanowire assuming a hexagonal cross section. We take the $x$ - and $s$-coordinates to parameterize the longitudinal direction of the wire and its perimeter, respectively. The vectors $\vec{B}$ and $\vec{n}$ represent the magnetic field and surface normal, respectively, and $\Phi$ is the angle between them. Points $s_{ \pm}$are midpoints on corresponding facets with fixed normal $\vec{n}_{ \pm}$. Facet length $L$ is fixed.

The previously mentioned examples referred to systems described by the Schrödinger equation. In more recent years, topological insulator (TI) ${ }^{20-23}$ have come to the forefront as materials that host surface states in nanowires ${ }^{24-29}$. This is due to the fact that TIs are characterized by an insulating bulk (either 3D or $2 \mathrm{D})$, but conducting surface states (2D or 1 D , respectively) whose low energy properties are described by the Dirac Hamiltonian, with a linear energy-momentum relation ${ }^{[2230]}$. These nanowires show rich AharanovBohm related phenomena ${ }^{31-35}$ for magnetic fields parallel to the nanowire axis $s^{24-29}$, or Landau level and snakelike states for transverse field $s^{36-43}$ that can give rise to rich transport phenomena, e.g., reversal of thermoelec-
tric currents ${ }^{433}$. Effective 2D models for TI nanowires have been used to investigate, e.g., Andreev reflection in T-junctions ${ }^{44}$, or cone shaped nanowires ${ }^{45}$. All the 2D models assume a fixed Fermi velocity, but for example in topological crystalline insulators different terminations of the crystalline lattice can host different velocities leading to hinge and corner states ${ }^{46][47]}$.

In this paper we consider the electronic properties of TI nanowires of polygonal shape in a constant transverse magnetic field. Different projections of the magnetic field along different polygon facets lead to energy spectra showing unique characteristics for each structure, e.g., two separate sets of Landau levels on different facets. We propose that the conductance of the wire, as a function of magnetic field orientation, can be used to differentiate between cross-sectional shapes of the nanowires. To model the transport we introduce a modified Wilson mass term which faithfully reproduces the correct Landau levels on different facets. We use the recursive Green's function method to calculate the transmission function and show that for low enough impurity densities the anisotropic conductance reveals the underlying nanowire shape.

The structure of the paper is as follows: Following the Introduction, the model system and Hamiltonian is discussed in Sec. II. We also outline the Landau level approximation for general facets of the polygon in Sec. IIA. The modification to the Wilson mass term for transport calculation is outlined in Sec. III along with transmission function calculations. The conductance anisotropy is discussed in Sec. IV, and finally we discuss the results in Sec. V.

## II. MODEL HAMILTONIAN AND FACET LANDAU LEVELS

We consider a nanowire composed of a TI material such that the wire surface can support edge modes, i.e., quasiparticles which propagate along the wire surface whilst the bulk remains insulating. Furthermore, we assume that there is a constant magnetic field perpendicular to the length of the wire. The wire surface is taken to be parameterized by $x$ and $s$, where $x$ spans the entire length of the wire and $s$ is the arc-length variable for the cross section perimeter of the wire, as shown in Fig. 1. The effective Hamiltonian describing the surface modes of such a system is ${ }^{48-50}$

$$
\begin{equation*}
H_{\mathrm{surf}}(x, s)=v_{F}\left\{\sigma_{x}\left[p_{x}+e A_{x}(s)\right]+\sigma_{y} p_{s}\right\} \tag{1}
\end{equation*}
$$

where $p_{s}=-i \hbar \partial_{s}$ is the momentum operator of the perimeter variable $s$. Here $v_{F}$ is the Fermi velocity, $e$ is the electronic charge, $\sigma_{x}$ and $\sigma_{y}$ are the Pauli matrices, $p_{x}$ is the momentum operator along the length of the wire, and $A_{x}$ is the $x$-component of the vector field. We choose the gauge such that $A_{y}=A_{z}=0$, and

$$
\begin{equation*}
A_{x}(y, z)=B[\sin (\phi) z-\cos (\phi) y] \tag{2}
\end{equation*}
$$

(a)

(b)

(c)

FIG. 2: Normalized vector potential, $A_{x}(s) / L B$, as a function of the perimeter variable $s$ for two different orientations of the magnetic field for different cross sections and orientation: a) triangle for $\phi=0$, and $\phi=\pi / 2$, b) square $\phi=0, \phi=\pi / 4$, and c) hexagon for $\phi=0$ and $\phi=\pi / 6$.
where $B=|\vec{B}|$ and $\phi$ is the angle between $\vec{B}$ and the $z$-axis. For the linear-in-momentum surface Hamiltonian the polygon corners have no effect on the surface states ${ }^{39[40] 51 / 52}$ and the influence of the polygonal shape only enters via discontinuities in the slope of $A_{x}(s)$.

In the absence of a magnetic field $H_{\text {surf }}$ admits a simple analytical spectrum. Squaring the Hamiltonian in Eq. (1) and using $\left\{\sigma_{x}, \sigma_{y}\right\}=0$ leads to

$$
\begin{equation*}
H_{\mathrm{surf}, 0}^{2}=\hbar^{2} v_{F}^{2}\left(p_{x}^{2}+p_{s}^{2}\right) \sigma_{0} \tag{3}
\end{equation*}
$$

with $\sigma_{0}$ being the $2 \times 2$ identity matrix. Applying the plane wave ansatz $\psi(x, s)=\frac{1}{\sqrt{L P}} e^{i\left(k_{x} x+k_{s} s\right)}$, where $L$ is the length of the wire and $P$ is the cross section perimeter length, yields eigenvalues of the form $E_{ \pm}= \pm \hbar v_{F} \sqrt{k_{x}^{2}+k_{s}^{2}}$. A nontrivial spin connection has been gauged away from the Hamiltonian and into the boundary condition $\psi(x, s+P)=-\psi(x, s)$, leading to $k_{s}=\frac{2 \pi}{P}\left(n+\frac{1}{2}\right)$ with integer $n \begin{aligned} & 31+33[53]\end{aligned}$.

## A. Facet Landau levels

In the presence of a perpendicular magnetic field the vector potential $A_{x}(s)$ changes according to the form of the prismatic nanowire. For translationally invariant wires where $\left[p_{x}, H_{\text {surf }}\right]=0, p_{x}$ can be replaced by its eigenvalue $\hbar k_{x}$ in Eq. (11). Depending on the orientation of the magnetic field, and the local normal $\vec{n}(s)$, Landau
levels can form at different facets, at different values of $k_{x}$. To illustrate how this occurs we consider the hexagonal nanowire with a magnetic field tilted from the $z$-axis by an angle $\phi$, and $\Phi$ is the angle between $\vec{B}$ and $\vec{n}$. Focusing on the tilted facets characterized by the two angles $\Phi_{+}$and $\Phi_{-}$, see Fig. 1 the vector potential can be linearized around the center on each facet, indicated by $s_{ \pm}$, resulting in

$$
\begin{equation*}
A_{x}^{ \pm}(s)=-B \cos \left(\Phi_{ \pm}\right)\left(s-s_{ \pm}\right)+A_{x}\left(s_{ \pm}\right) \tag{4}
\end{equation*}
$$

The resulting linearized version of Eq. (11) is then

$$
\begin{align*}
& H_{\mathrm{surf}}^{[ \pm]}=v_{F}\left\{\sigma_{x}\left[-e B^{ \pm}\left(s-s_{ \pm}\right)+\hbar k_{x}+e A_{x}\left(s_{ \pm}\right)\right]\right. \\
&\left.+\sigma_{y} p_{s}\right\} \tag{5}
\end{align*}
$$

where $B^{ \pm}=B \cos \left(\Phi_{ \pm}\right)$. Landau levels centered on $s_{ \pm}$ will form at $k_{x}$-values that satisfy $\hbar k_{x}+A_{x}\left(s_{ \pm}\right)=0$, see App. A. Moving away from these $k_{x}$-values by $\Delta k_{x}$ shifts the Landau level center coordinate by $\Delta s_{ \pm}=\frac{\hbar}{e B^{ \pm}} \Delta k_{x}$.

The properties of $A_{x}$ as a function of the perimeter variable $s$ are shown in Fig. 2, for a) a triangle, b) a square, and c) a hexagon. The coordinate system is chosen such that the $x$-axis (the longitudinal direction) intersects the centroid of the nanowire, and $s=0$ is placed at the top left corner of each shape, and increases in the clockwise direction. The slope of each piece-wise linear part gives the normal projection of the magnetic field on the corresponding facet. Two different orientations of magnetic fields are shown for each shape. The blue and red dots indicate the position of the $s$-points (for $k_{x}=0$ ), where Landau levels will be centered, which depends on the cross section shape and magnetic field orientation. Focusing on one such $k_{x}$ value, e.g., for $s_{+}$the Hamiltonian can be written as

$$
\begin{equation*}
H_{\mathrm{surf}}^{[+]}=\frac{\hbar v_{F} \sqrt{\left|\cos \left(\Phi_{+}\right)\right|}}{\sqrt{2} \ell_{c}}\left(a_{[+]} \sigma_{+}+a_{[+]}^{\dagger} \sigma_{-}\right) \tag{6}
\end{equation*}
$$

where $\sigma_{ \pm}=\sigma_{x} \pm i \sigma_{y}, \ell_{c}^{2}=\hbar / e B$ is the magnetic length, and the ladder operator for the $\vec{n}_{+}$facet is defined in in Eq. (A4) in App. A, Being able to focus on a given facet and defining the facet Hamiltonian in Eq. (6) relies on the wave function being nonzero only on that facet (up to exponentially small corrections). In terms of the magnetic length $\ell_{c}$ and side length $L$ this condition translates to $\ell_{c} / L \ll \sqrt{\left|\cos \left(\Phi_{+}\right)\right|}$. The Hamiltonian in Eq. (6) can be diagonalized using basis states $\{|n-1, \uparrow\rangle,|n, \downarrow\rangle\}$ for $n=1,2,3, \ldots$ resulting in a pair of eigenenergies (negative and positive)

$$
\begin{equation*}
\varepsilon_{n, \pm}^{[+]}= \pm \frac{\hbar v_{F} \sqrt{\left|\cos \left(\Phi_{+}\right)\right|}}{\ell_{c}} \sqrt{2 n} \tag{7}
\end{equation*}
$$

along with a single state $|0, \downarrow\rangle$ with eigenenergy $\varepsilon_{0}^{[+]}=0$. In a similar way the Hamiltonian for the $\vec{n}_{-}$segment can be written as

$$
\begin{equation*}
H_{\mathrm{surf}}^{[-]}=\frac{\hbar v_{F} \sqrt{\left|\cos \left(\Phi_{-}\right)\right|}}{\sqrt{2} \ell_{c}}\left(a_{[-]}^{\dagger} \sigma_{+}+a_{[-]} \sigma_{-}\right) \tag{8}
\end{equation*}
$$

FIG. 3: Energy spectra for the triangle for the two magnetic field orientations shown in Fig. 2k). The magnetic field value corresponds to $\ell_{c} / L=0.125$. The two dashed lines indicate energies $E=0.97$ and 1.92 that are relevant for subsequent transport calculations. The vertical dash-dotted line indicates the $k_{x} L$-value corresponding to the center of the facet where the zero-magnetic field states occur, see text for details. The zero energy Landau levels are doubly degenerate.
where the corresponding ladder operator is defined in Eq. (A6) in App. A The Hamiltonian in Eq. (8) can be diagonalized with the basis states $\{|n-1, \downarrow\rangle,|n, \uparrow\rangle\}$ for $n=1,2,3, \ldots$, where the spin indices have been switched. The resulting pair of eigenenergies (negative and positive)

$$
\begin{equation*}
\varepsilon_{n, \pm}^{[-]}= \pm \frac{\hbar v_{F} \sqrt{\left|\cos \left(\Phi_{-}\right)\right|}}{\ell_{c}} \sqrt{2 n} \tag{9}
\end{equation*}
$$

along with a single state $|0, \uparrow\rangle$ with eigenenergy $\varepsilon_{0}^{[-]}=0$.
The energy spectrum, as a function of $k_{x}$, for a triangular nanowire is shown in Fig. 3 for the two different magnetic field orientations shown in Fig. 2a). Only the positive energy is shown since the negative part is simply mirrored due to an electron-hole symmetry, i.e., the anticommutation relation $\left\{H_{\text {surf }}, \sigma_{z}\right\}=0$ results in any state $|\psi\rangle$ with energy $\varepsilon \geq 0$ having a corresponding state $\sigma_{z}|\psi\rangle$ with negative energy $-\varepsilon$. For magnetic field orientation $\phi=0$ the tilted facets of the triangle have $\cos \left(\Phi_{+}\right)=1 / 2$ and on the bottom facet $\left|\cos \left(\Phi_{-}\right)\right|=1$. The spectrum shows an interesting feature of every other LL being nondegenerate at energies $\sqrt{1}, \sqrt{3}, \sqrt{5}, \ldots$ (in units of $\hbar v_{F} / \ell_{c}$ ) while LL at energies $\sqrt{0}, \sqrt{2}, \sqrt{4}, \ldots$ are doubly degenerate. The LL energies, given by Eqs. (7) and (9), coincide if $\left|\cos \left(\Phi_{+}\right)\right| m_{+}=\left|\cos \left(\Phi_{-}\right)\right| m_{-}$where $m_{ \pm} \in \mathbb{N}$ are the LL indices for the $\Phi_{ \pm}$facets (the $\Phi_{+}$facet consists of the top left and right facets). This happens for the even $m_{+}$states on the $\Phi_{+}$facet which will hybridize with the state on the opposing facet, into symmetric and anti-symmetric states, as they evolve into linear-in $k_{x}$ states for $\left|k_{x}\right| \gg L / \ell_{c}^{2}$. The odd $m_{+}$states on the $\Phi_{+}$ facet never coincide with the eigenenergies of states on

FIG. 4: Energy spectra for the square for the two magnetic field orientations shown in Fig. 2b). The magnetic field value corresponds to $\ell_{c} / L=0.125$. The two dashed lines indicate energies $E=0.97$ and 1.92 that are relevant for subsequent transport calculations. The vertical dash-dotted lines indicates the $k_{x} L$-values where the zero-magnetic field states occur, see text for details. The zero energy Landau levels are doubly degenerate.
opposite facets. As $k_{x}$ is increased these states will be coupled to states with different energies (2nd order perturbation) without hybridizing, as they evolve into linearin $k_{x}$ states for $\left|k_{x}\right| \gg L / \ell_{c}^{2}$.

In the $\phi=\pi / 2$ orientation the magnetic field is parallel to the bottom side, leading to a zero-magnetic field projection on that facet. The two tilted facets will have opposite projection and will hybridize at the apex for positive value of $k_{x}$. For negative values of $k_{x}$ the wave function is pushed toward the $\overrightarrow{\boldsymbol{B}} \cdot \overrightarrow{\boldsymbol{n}}=0$ facet. This corresponds to the red curve in Fig. 2 a , where one can see that $A_{x}(s)$ is constant for $s \in[L, 2 L]$. Setting $s=3 L / 2$, corresponding to the center of the constant region, results in a value of $k_{x} L$ that is determined by

$$
\begin{equation*}
\hbar k_{x}+\left.e A_{x}(s)\right|_{s=3 L / 2}=0 \tag{10}
\end{equation*}
$$

Note the coordinate system is placed in the centroid of the triangle which, in our chosen gauge, results in $A_{x}(s)=-\frac{\sqrt{3}}{4} B L$ in the constant region. The resulting value $k_{x} L=\frac{\sqrt{3} L^{2}}{4 \ell_{c}^{2}}$ is indicated by a vertical line for $\phi=\pi / 2$. A set of states will form there which, to lowest order, have energies $\sim \hbar v_{F} \frac{\pi}{L} \times$ integer.

Figure 4 shows the square nanowire spectra for two magnetic field orientations. For $\phi=0$ the two side facets have zero projection of the magnetic field so that for $\left|k_{x} L\right| \sim L^{2} / 2 \ell_{c}^{2}$ the Landau levels evolve into corresponding quantized zero-magnetic field states. The $s$-values at the center of the flat sections of $A_{x}(s)$ in Fig. 20 are $s=3 L / 2$ and $7 L / 2$. In this case, the condition in Eq. (10) results in $\left|k_{x} L\right|=L^{2} / 2 \ell_{c}^{2}$, indicated by the vertical dashed line. Note that each Landau level evolves into two states on the side facet, the same applies to the zero Landau level which is doubly degenerate and

FIG. 5: Energy spectra for the hexagon for the two magnetic field orientations shown in Fig. 2k). The magnetic field value corresponds to $\ell_{c} / L=0.125$. The two dashed lines indicate energies $E=0.97$ and 1.92 that are relevant for subsequent transport calculations. The vertical dash-dotted lines indicates the $k_{x} L$-values where the zero-magnetic field states occur, see text for details. The zero energy Landau levels are doubly degenerate.
splits into a positive energy state and a negative energy state (not shown). For the $\phi=\pi / 4$ orientation the magnetic field projection is never zero and takes constant value $\cos \left(\Phi_{+}\right)=1 / \sqrt{2}$ for the two facets with positive projection, but $\cos \left(\Phi_{-}\right)=-1 / \sqrt{2}$ for the negative projection facets. For $\left|k_{x} L\right| \sim L^{2} / 2 \ell_{c}^{2}$ the Landau levels hybridize and evolve towards a linear in $k_{x}$ dependence when $\left|k_{x} L\right| \gg L^{2} / \ell_{c}^{2}$. The dispersing states occur in the two corners where $\overrightarrow{\boldsymbol{B}} \cdot \overrightarrow{\boldsymbol{n}}$ changes sign.

The hexagon is the final shape we consider. The energy spectra for the two orientations in Fig. 2F are shown in Fig. 5. For the $\phi=\pi / 6$ orientation the spectrum is similar to the $\phi=0$ spectrum for the square in Fig. 4] since on two facets $\overrightarrow{\boldsymbol{B}} \cdot \overrightarrow{\boldsymbol{n}}=0$, and on the remaining facets $\cos \left(\Phi_{+}\right)=\left|\cos \left(\Phi_{-}\right)\right|=\sqrt{3} / 2$. The zero-magnetic field states, where $\overrightarrow{\boldsymbol{B}}$ is parallel to the facets (red curve in Fig. 2k), are determined by Eq. (10) at $s=5 L / 2$ and $11 L / 2$. These value of $s$ on the hexagon result in $k_{x} L=$ $\pm \sqrt{3} L / 2 \ell_{c}^{2}$, indicated by the vertical lines. The $\phi=0$ orientation for the hexagon shows that Landau levels can form on two facets with the same sign of $\cos \left(\Phi_{+}\right)$, but different values reflecting the different facet orientation. On the top surface $\cos \left(\Phi_{+}\right)=1$ but on the adjacent facet $\cos \left(\Phi_{+}\right)=1 / 2$ resulting in $\varepsilon_{1,+}=1$, in units of $\frac{\hbar v_{F}}{\ell_{c}}$. The effectively smaller magnetic field on the tilted facets translates to a smaller width of the Landau levels, i.e., smaller $k_{x}$ interval, before they hybridizes with the states on the facets with the opposite projection.

The energy spectra in Figs. 3 3 are obtained by direct numerical diagonalization of Eq. (1) written in a basis of 76 plane wave basis states, see below Eq. (3), along with the two spin states. The number of basis states is chosen such that the first 10 Landau levels (flat) conincide with
the analytical energy levels for the facets given in Eqs. (7) and (9).

## III. LATTICE MODEL IN THE PRESENCE OF IMPURITIES

In the previous section we analyzed the Landau levels forming on different facets assuming translational invariance along the wire. In the presence of impurities $k_{x}$ is no longer a good quantum number and we need to solve the Dirac eigenvalue problem in terms of both the surface variables $(x, s)$. To model the effect of randomly distributed point impurities on the transport properties of the wire we discretize the longitudinal $(x)$ variable of $H_{\text {surf }}(x, s)$ using a finite difference approach with a lattice constant $a$. This entails approximating the action of $\partial_{x}$ onto the spatial component $\psi(x, s)$ of the wave function as

$$
\begin{equation*}
\partial_{x} \psi(x, s) \approx \frac{1}{2 a}[\psi(x+a, s)-\psi(x-a, s)] \tag{11}
\end{equation*}
$$

such that the Hamiltonian is approximated as

$$
\begin{align*}
H_{\mathrm{surf}} \psi(x, s) & \approx v_{F}\left[e \sigma_{x} A_{x}(s)-i \hbar \sigma_{y} \partial_{s}\right] \psi(x, s) \\
& -\frac{i \hbar v_{F} \sigma_{x}}{2 a}[\psi(x+a, s)-\psi(x-a, s)] \tag{12}
\end{align*}
$$

Discretizing the linear in momentum Hamiltonian in Eq. (11) will lead to Fermion doubling $[54 \mid 55]$ For twodimensional linearly dispersing Hamiltonians an extra quadratic term can be added to solve the Fermion doubling ${ }^{[56 \mid[57]}$

$$
\begin{equation*}
H_{W}=\frac{v_{F} \beta}{\hbar}\left\{\sigma_{z}\left[\left(p_{x}+e A_{x}(s)\right)^{2}+p_{s}^{2}\right]\right\} \tag{13}
\end{equation*}
$$

where $\beta$ is a parameter with dimension of length. The value of $\beta=a / \sqrt{3}$ gives a linear in momentum dependence of $k_{x}$ over a large part of the Brillouin zone, but still lifts the Fermion doubling ${ }^{588}$.

Although the Hamiltonian in Eq. (13) solves the Fermion doubling it will lead to a shift of the Landau levels, which is in opposite direction depending on the projection of $\vec{B}$ on the local normal $\vec{n}(s)$. To illustrate this energy shift, and also show how it can remedied, we solve the facet Landau levels in the presence of $H_{W}$ in Eq. (13) for the homogeneous wire. Starting with the definition of the ladder operators for the positive projection in Eq. (44) and applying it to $H_{\text {surf }}^{[+]}+H_{W}$ results in

$$
\begin{align*}
& H_{\mathrm{surf}, W}^{[+]}=\frac{\hbar v_{F} \sqrt{\left|\cos \left(\Phi_{+}\right)\right|}}{\sqrt{2} \ell_{c}}\left[a_{[+]} \sigma_{+}+a_{[+]}^{\dagger} \sigma_{-}\right. \\
& \left.\quad+\quad \sigma_{z} 2 \sqrt{2} \sqrt{\left|\cos \left(\Phi_{+}\right)\right|} \frac{\beta}{\ell_{c}}\left(a_{[+]}^{\dagger} a_{[+]}+\frac{1}{2}\right)\right], \tag{14}
\end{align*}
$$

which has shifted the previously zero energy eigenstate $|0, \downarrow\rangle$ and the other eigenenergies are found by diagonalization in the basis $\{|n-1, \uparrow\rangle,|n, \downarrow\rangle\}, n=1,2, \ldots$ The resulting eigenenergies are

$$
\begin{align*}
\varepsilon_{0}^{[+]} & =-\frac{\hbar v_{F}}{\ell_{c}} \frac{\beta}{\ell_{c}}\left|\cos \left(\Phi_{+}\right)\right|  \tag{15}\\
\varepsilon_{n, \pm}^{[+]} & =\frac{\hbar v_{F}}{\ell_{c}}\left(-\frac{\beta}{\ell_{c}}\left|\cos \left(\Phi_{+}\right)\right|\right. \\
& \left. \pm \frac{\sqrt{\left|\cos \left(\Phi_{+}\right)\right|}}{\sqrt{2}} \sqrt{4 n+8\left|\cos \left(\Phi_{+}\right)\right| \frac{\beta^{2}}{\ell_{c}^{2}} n^{2}}\right) \tag{16}
\end{align*}
$$

For the negative projection Landau levels, the same procedure starting from Eq. (8) and the definition of ladder operators in Eq. (A6) results in the following Hamiltonian

$$
\begin{align*}
& H_{\mathrm{surf}, W}^{[-]}=\frac{\hbar v_{F} \sqrt{\left|\cos \left(\Phi_{-}\right)\right|}}{\sqrt{2} \ell_{c}}\left[a_{[-]}^{\dagger} \sigma_{+}+a_{[-]} \sigma_{-}\right. \\
& \left.\quad+\quad \sigma_{z} 2 \sqrt{2} \sqrt{\left|\cos \left(\Phi_{-}\right)\right|} \frac{\beta}{\ell_{c}}\left(a_{[-]}^{\dagger} a_{[-]}+\frac{1}{2}\right)\right] \tag{17}
\end{align*}
$$

Now, the shifted zero energy state is $|0, \uparrow\rangle$ and other eigenergies are obtained by diagonalizing in the basis $\{|n-, \downarrow\rangle,|n, \uparrow\rangle\}, n=1,2, \ldots$ The resulting eigenenergies are

$$
\begin{align*}
\varepsilon_{0}^{[-]} & =\frac{\hbar v_{F}}{\ell_{c}} \frac{\beta}{\ell_{c}}\left|\cos \left(\Phi_{-}\right)\right|  \tag{18}\\
\varepsilon_{n+1,+}^{[-]} & =\frac{\hbar v_{F}}{\ell_{c}}\left(\frac{\beta}{\ell_{c}}\left|\cos \left(\Phi_{-}\right)\right|\right. \\
\pm & \left.\frac{\sqrt{\left|\cos \left(\Phi_{-}\right)\right|}}{\sqrt{2}} \sqrt{4 n+8\left|\cos \left(\Phi_{-}\right)\right| \frac{\beta^{2}}{\ell_{c}^{2}} n^{2}}\right) . \tag{19}
\end{align*}
$$

On inspection of Eqs. (15)-(16) and (18)-(19), one can see that the shift that breaks the Landau level degeneracy can be removed by adding a term $v_{F} \beta e B \cos (\Phi)=$ $v_{F} \beta e \vec{B} \cdot \vec{n}(s)$. The amended Wilson mass term accounting for different orientation of surface normals with respect to the applied magnetic field is thus

$$
\begin{equation*}
H_{W, B}=\frac{v_{F} \beta}{\hbar}\left\{\sigma_{z}\left[\left(p_{x}+e A_{x}(s)\right)^{2}+p_{s}^{2}\right]+\sigma_{0} \frac{e}{\hbar} \vec{B} \cdot \vec{n}(s)\right\} \tag{20}
\end{equation*}
$$

We can now discretize $H_{\text {surf }}+H_{W, B}$, given by Eqs. (11) and (20), respectively, in the $x$-variable (see App. B for details) and model randomly placed short range impurities with

$$
\begin{equation*}
V(x, s)=\sum_{n} V_{\mathrm{imp}} \delta\left(s-s_{n}\right) \delta\left(x-x_{n}\right) \tag{21}
\end{equation*}
$$

where $V_{\mathrm{imp}}$ is the impurity strength. The density of impurities is controlled by the parameter $a_{\mathrm{imp}}$, which gives the average distance between impurities in units of $a$.

FIG. 6: The transmission function $T(E)$ for a) triangle, b) square, and c) hexagon. The curves corresponding to different impurity densities are offset for clarity. For comparison, the gray lines show $T(E)$ for the clean wire shifted by $\Delta E=\langle V\rangle$. The impurity strength is $V_{\mathrm{imp}}=0.45 \frac{\hbar v_{F}}{\ell_{c}}, a=0.0025 L, N_{x}=$ 2400, and $l_{c} / L=0.20$. The arrows indicate prevalent step sizes $\Delta T$.

We then use standard transport methods based on the recursive Green's functions method $\sqrt{59 / 60}$. This is outlined in the case of circular nanowires in Ref. ${ }^{[43}$, which can be directly applied here by replacing the cylindrical perimeter $R \varphi$ with the equivalent polygonal perimeter variable $s$. From the nanowire Green's function one obtains the transmission function $T(E) \cdot{ }^{[59}$

In Fig. 6 we show the transmission function for the three cross-sectional shapes, a) triangle, b) square, and c) hexagon. The transmission calculations are done for a single impurity configuration, i.e. there is no averaging over impurity configurations. The different curves, which are offset for clarity, correspond to increased impurity concentrations, parameterized by $\frac{a_{\text {imp }}}{a}$. Narrow features in $T(E)$ tend to get washed out by increased impurity concentration, but for all cases considered here
the quantized steps are quite evident. Note that in Fig. 6b (square) and Fig. 6; (hexagon), the transmission steps are of size $\Delta T=2$, but for the triangle in Fig. 6a the step size is predominantly of size $\Delta T=1$. This is due to the nondegenerate Landau levels and asymmetric zeromagnetic field states in the triangle shown in Fig. 3 which contribute only one conducting channel.

Note that the curves corresponding to clean systems show no spurious levels splitting due to the Wilson mass term. Experimentally there are already transport measurements that show evidence of quantized TI nanowire states ${ }^{28 /[29}$. For such samples the nanowire cross-sectional shape can be identified from transport properties, as we will discuss in the next section.

## IV. CONDUCTANCE AND MAGNETIC FIELD ORIENTATION

Having established an accurate method of calculating transmission function in TI prismatic nanowires we can make predictions regarding the two terminal conductance, and how it behaves as a function of magnetic field orientation. In Fig. 7 we plot the conductance for a) triangle, b) square, and c) hexagon, as a function of magnetic field orientation angle $\phi$. There are two features that allow us to identify the shape of the nanowire from this: $(i)$ the number of times repeated features appear in $G_{c}(\phi)$ for $\phi \in[-\pi / 2, \pi / 2]$, and (ii) how large the conductance steps are. In Fig. 7b) the features is $G_{c}(\phi)$ are repeated twice, for both energies, indicating an underlying square cross-section. The number of repeating patterns in Figs. 73) and 7r) is three, reflecting the underlying three-fold symmetry of both triangle and hexagon. However, the step sizes are different: $\Delta G_{c}=1$ for the triangle and $\Delta G_{c}=2$ for the hexagon. The origin of the difference can be understood by comparing Fig. 3 for $\phi=\pi / 2$ (triangle), and Fig. 5 for $\phi=\pi / 3$ (hexagon). For the triangle only one facet can be parallel to the applied magnetic field. This leads to the observed asymmetry in the energy spectrum. As the magnetic field rotates the zero-magnetic field states move up or down relative to $E$ leading to jumps of $\Delta G_{c}=1$. In the case of the hexagon, two facets can be parallel to the applied $B$-field. This leads to two sets of such zero-magnetic field states which results in $\Delta G_{c}=2$, as is observed in Fig. (77).

As can be seen in Fig. 6a (triangle) steps of $\Delta T=2$ are possible for certain energies (see $E=1.33$ for the clean wire). But if the $G_{c}(\phi)$ can be measured for different energies, then it should possible to establish whether $\Delta T=2$ is predominant (hexagon) or $\Delta T=1$ is predominant (triangle).

## V. CONCLUSIONS

We have studied surface electrons in nanowires made of a TI material, in the presence of an external mag-

FIG. 7: Conductance $G_{c}$ as a function of angle $\phi$ for a) triangle, b) square, and c) hexagon. The conductance is calculated at two energies for each shape, corresponding to the vertical lines in Figs. 3.5, with $l_{B} / L=0.125$. The arrows denote the size of the conductance jumps $\Delta G_{c}$.
netic field perpendicular to the longitudinal axis of the nanowire. The cross section of the nanowire is considered polygonal, as in most of the experimental realizations. In the present work we have discussed the triangular, square, and hexagonal cases. The component of the magnetic field normal to the electrons' trajectories depends on the facet of the prism, and consequently peculiar energy spectra are obtained, combining local Landau levels with free motion. We have shown that the transmission function depends on the cross sectional geometry. And, naturally, for each geometry the conductance is anisotropic, i.e., it changes with the angular direction of the magnetic field.

These results can be useful to characterize the real TI nanowires fabricated in the labs ${ }^{28 \mid 29}$. The presence of the conduction electrons on the surface and the polygonal cross section (often hexagonal) should lead to conductance features that we described, which should be robust
in the presence of a modest amount of disorder. The sample quality can therefore be tested, for example by rotating the sample or the magnetic field (in a vector magnetic system), and comparing the conductance with the external geometry of the nanowire.

## Appendix A: Facet orientation and ladder operators

We start with the linearized surface Hamiltonian in Eq. (51). Intoducing the $k_{x}$-dependent center coordinate

$$
\begin{equation*}
s_{ \pm}\left(k_{x}\right) \equiv s_{ \pm}+\frac{e A_{x}\left(s_{ \pm}\right)+\hbar k_{x}}{e B^{ \pm}} \tag{A1}
\end{equation*}
$$

Eq. (5) can be written as

$$
\begin{equation*}
H_{\mathrm{surf}}^{[ \pm]}=v_{F}\left\{\sigma_{x}\left[-e B_{ \pm}\left(s-s_{ \pm}\left(k_{x}\right)\right)\right]+\sigma_{y} p_{s}\right\} \tag{A2}
\end{equation*}
$$

where $B^{ \pm}=B \cos \left(\Phi_{ \pm}\right)$. Rewriting Eq. (A2) in terms of $\sigma_{ \pm}=\sigma_{x} \pm i \sigma_{y}$ results in

$$
\begin{align*}
H_{\mathrm{surf}}^{[ \pm]}=v_{F} & \left\{\frac{\sigma_{+}}{2}\left[-e B_{ \pm}\left(s-s_{ \pm}\left(k_{x}\right)\right)-i p_{s}\right]\right. \\
& \left.+\frac{\sigma_{-}}{2}\left[-e B_{ \pm}\left(s-s_{ \pm}\left(k_{x}\right)\right)+i p_{s}\right]\right\} \tag{A3}
\end{align*}
$$

The sign of $\cos \left(\Phi_{ \pm}\right)$will determine the how the ladder operators are defined in terms of $s$ and $p_{s}$, as we show below. For concreteness we now assume $\cos \left(\Phi_{+}\right)>0$. The requirement $\left[a, a^{\dagger}\right]=1$, fixes the definition of the ladder operator on that facet, i.e.

$$
\begin{equation*}
a_{[+]}=\frac{\ell_{c}}{\sqrt{2} \hbar \sqrt{\left|\cos \left(\Phi_{+}\right)\right|}}\left[-\frac{\hbar}{\ell_{c}^{2}} \cos \left(\Phi_{+}\right)\left(s-s_{+}\right)+i p_{s}\right] . \tag{A4}
\end{equation*}
$$

In terms of these ladder operators the surface Hamiltonian of the facet is

$$
\begin{equation*}
H_{\mathrm{surf}}^{[+]}=\frac{\hbar v_{F} \sqrt{\left|\cos \left(\Phi_{+}\right)\right|}}{\sqrt{2} \ell_{c}}\left(a_{[+]} \sigma_{+}+a_{[+]}^{\dagger} \sigma_{-}\right) . \tag{A5}
\end{equation*}
$$

The zero energy state of the above Hamiltonian is $|0\rangle|\downarrow\rangle$ since $a_{[+]} \sigma_{+}|0\rangle|\downarrow\rangle=0$, and $a_{[+]}^{\dagger} \sigma_{-}|0\rangle|\downarrow\rangle=0$.

Repeating the same proceedure for the other facet results in the ladder operator

$$
\begin{equation*}
a_{[-]}=\frac{\ell_{c}}{\sqrt{2} \hbar \sqrt{\left|\cos \left(\Phi_{-}\right)\right|}}\left[\frac{\hbar}{\ell_{c}^{2}} \cos \left(\Phi_{-}\right)\left(s-s_{+}\right)-i p_{s}\right], \tag{A6}
\end{equation*}
$$

and the corresponding surface Hamiltonian of the facet

$$
\begin{equation*}
H_{\mathrm{surf}}^{[-]}=\frac{\hbar v_{F} \sqrt{\left|\cos \left(\Phi_{-}\right)\right|}}{\sqrt{2} \ell_{c}}\left(a_{[-]}^{\dagger} \sigma_{+}+a_{[-]} \sigma_{-}\right) \tag{A7}
\end{equation*}
$$

Again, the zero energy state of the above Hamiltonian is $|0\rangle|\uparrow\rangle$, since $a_{[-]}^{\dagger} \sigma_{+}|0\rangle|\uparrow\rangle=0$, and $a_{[-]} \sigma_{-}|0\rangle|\uparrow\rangle=0$.

## Appendix B: Discretization with quadratic term

Starting from Eq. (12), it can be written as

$$
\begin{equation*}
H_{\text {surf }} \psi(x, s)=H_{0} \psi(x, s)+V \psi(x+a, s)+V^{\dagger} \psi(x-a, s) \tag{B1}
\end{equation*}
$$

where $H_{0}=v_{F}\left(e \sigma_{x} \hat{A}_{x}(s)-i \hbar \sigma_{y} \partial_{s}\right)$ acts as an on-site potential of the lattice points and $V=-\frac{i \hbar v_{F}}{2 a} \sigma_{x}$ acts as a nearest neighbour coupling term.

Just as for the continuous model, the discrete model admits a simple analytical expression for its energy spectrum when the magnetic field is absent. Applying a Bloch ansatz $\psi(x, s)=e^{i k_{x} x} \phi_{k_{x}}(s)$ results in

$$
\begin{aligned}
H_{\mathrm{surf}} \psi(x, s) & =\left(\hat{H}_{0}+\hat{V} e^{i k_{x} a}+\hat{V}^{\dagger} e^{-i k_{x} a}\right) e^{i k_{x} x} \phi_{k_{x}}(s) \\
& =\hbar v_{F}\left(\frac{\sin \left(k_{x} a\right)}{a} \sigma_{x}+k_{s} \sigma_{y}\right) e^{i k_{x} x} \phi_{k_{x}}(s)
\end{aligned}
$$

which leads to eigenvalues

$$
\begin{equation*}
E_{ \pm}= \pm \hbar v_{F} \sqrt{\frac{\sin ^{2}\left(k_{x} a\right)}{a^{2}}+k_{s}^{2}} \tag{B2}
\end{equation*}
$$

which will converge to the spectrum of the continuous model in the limit $a \rightarrow 0$. The anti-periodic boundary conditions is inherited by $\phi_{k_{x}}$, i.e., $\phi_{k_{x}}(s)=-\phi_{k_{x}}(s+P)$, which results in $k_{s}=\frac{2 \pi}{P}\left(n+\frac{1}{2}\right)$ with integer $n$.

There is however a serious issue with the discrete spectrum solution which is that it will close around the edges of the Brillouin zone ( $k_{x}= \pm \pi / a$ ), effectively doubling the number of modes. This is the well known Fermion doubling problem. As it is an unwanted consequence of projecting our model onto a lattice, we remedy the problem by adding a Wilson mass term [Eq. (13)] to our surface model. The finite difference version of the quadratic term yields

$$
\begin{equation*}
\partial_{x}^{2} \psi(x, s) \approx \frac{[\psi(x+a, s)-2 \psi(x, s)+\psi(x-a, s)]}{a^{2}} \tag{B3}
\end{equation*}
$$

such that the on-site potential and nearest neighour terms become

$$
\begin{align*}
H_{0} & =v_{F}\left[e \sigma_{x} \hat{A}_{x}(s)-i \hbar \sigma_{y} \partial_{s}+\frac{\beta}{\hbar} \sigma_{z}\left(\frac{2 \hbar^{2}}{a^{2}}+e^{2} \hat{A}_{x}^{2}(s)\right)\right] \\
V & =v_{F}\left[-\frac{i \hbar}{2 a} \sigma_{x}+\frac{\beta}{\hbar} \sigma_{z}\left(-\frac{\hbar^{2}}{a^{2}}-\frac{i \hbar e \hat{A}_{x}(s)}{a}\right)\right] . \tag{B4}
\end{align*}
$$

For $B=0$, the plane wave solution now results in

$$
\begin{align*}
H_{\text {surf }} \psi(x, s)=\hbar v_{F} & {\left[\frac{\sin \left(k_{x} a\right)}{a} \sigma_{x}+4 \beta \frac{\sin ^{2}\left(k_{x} a / 2\right)}{a^{2}} \sigma_{z}\right.} \\
& \left.+k_{s}^{2} \sigma_{y}\right] e^{i k_{x} x} \phi_{k_{x}}(s) \tag{B6}
\end{align*}
$$

and corresponding eigenvalues

$$
\begin{equation*}
E_{ \pm}= \pm \hbar v_{F} \sqrt{\frac{\sin ^{2}\left(k_{x} a\right)}{a^{2}}+16 \beta^{2} \frac{\sin ^{4}\left(k_{x} a / 2\right)}{a^{4}}+k_{s}^{2}} \tag{B7}
\end{equation*}
$$

Taylor expanding the sinusoidal terms involving $k_{x}$ gives

$$
\begin{equation*}
\frac{\sin ^{2}\left(k_{x} a\right)}{a^{2}}+16 \beta^{2} \frac{\sin ^{4}\left(k_{x} a / 2\right)}{a^{4}} \approx k_{x}^{2}+\left(\beta^{2}-\frac{a^{2}}{3}\right) k_{x}^{4} \tag{B8}
\end{equation*}
$$

which implies that the linear behaviour of the energy spectrum is best maintained by setting $\beta=\frac{a / 58}{\sqrt{3}}$. In addition to maintaining the structure of the Dirac cone around the origin, the Wilson mass term succeeds in "lifting away" the spurious Dirac cone at the edges of the Brillouin zone. We can see this by considering the lowest energy modes at the edges where we have $E_{ \pm}\left(k_{x}= \pm \pi / a, k_{s}=0\right)= \pm \hbar v_{F} \frac{4}{a \sqrt{3}}$ such that the Dirac cone can always be lifted further away by decreasing the lattice constant $a$. Note also that in the limit of $a \rightarrow 0$ that the energy spectrum converges to the one of the continuum model.

Having $H_{0}$ and $V$, along with an appropriate impurity potential $V_{\mathrm{imp}}$, defined they can then be written as matrices, indicated by $[\cdot]$, in a truncated basis of plane waves along the perimeter, and the spin basis. The Green's function lattice equation then becomes

$$
\begin{equation*}
(E[\mathbb{I}]-[H]) G_{i, j}-[V] G_{i+1, j}-\left[V^{\dagger}\right] G_{i-1, j}=[\mathbb{I}] \delta_{i, j} \tag{B9}
\end{equation*}
$$

where $[H]=\left[H_{0}\right]+\left[V_{\mathrm{imp}}\right]$ and $i, j$ are lattice positions along the wire. The above equation can then be implemented using standard recursive GF method ${ }^{43 / 59 / 60]}$.
