## ABSTRACT

Internet-of-Things devices, ranging from smart home assistants to health devices, are pervasive: Forecasts estimate their number to reach 29 billion by 2030. Understanding the security of their machine-to-machine communication is crucial. Prior work focused on identifying devices’ vulnerabilities or proposed protocol-specific solutions. Instead, in this paper, we investigate the security of backends speaking Internet-of-Things (IoT) protocols at scale, that is, the backbone of the entire IoT ecosystem.

We focus on three real-world protocols used by IoT for our large-scale analysis: MQTT, CoAP, and XMPP. We gather a dataset of over 337,000 backends, augment it with geographical and provider data, and perform non-invasive active measurements to investigate three major security threats: information leakage, weak authentication, and denial of service. Our results provide quantitative evidence of a problematic immaturity in the IoT security ecosystem. Among other issues, we find that 9.44% backends expose information, 30.38% CoAP-speaking backends are vulnerable to denial of service attacks, and 99.84% of MQTT-speaking and XMPP-speaking backends use insecure transport protocols (only 0.16% adopt TLS, of which 70.93% adopt a vulnerable version).

## 1 INTRODUCTION

The number of active Internet of Things (IoT) devices peaked at 13 billion in 2022, with forecasts estimating more than 29 billion devices by 2030, highlighting the considerable impact they have [98]. They assist people with health sensors and improve living conditions with smart home systems (e.g., alarms and thermostats) or smart city solutions (e.g., air quality monitors). These devices typically rely on backends, that is, *servers, commonly deployed in the cloud, that store and process data from the devices and can control the connected devices*. Backends play a vital role in the IoT ecosystem, and their security is crucial. A vulnerable backend can enable a variety of attacks, for example, information exfiltration or Denial of Service (DoS). Such attacks are far from hypothetical and unprecedented in their scale due to the IoT devices’ pervasiveness [29, 91]. Sabetan [81] discovered that over 40,000 Nexx’s Smart Garage doors were vulnerable due to a misconfigured Message Queue Telemetry Transport (MQTT) broker. An attacker could have opened any garage door from anywhere in the world as a single insecure password was used to protect data for all customers.

Several issues also arose with connected kids’ devices and their insecure backends [32, 51, 34]. CloudPets allowed parents and kids to record and receive audio files through Internet-connected plush toys. Hunt et al. [33, 54] could access over 2M recordings of over 800k users containing personal conversations as they were stored in a MongoDB database with hardly any authentication.

There are only few standardized attempts and best practices for securing the IoT ecosystem, like Manufacturer Usage Descriptions (MUDs) [23, 46, 25], but they are only high-level descriptions and not yet deployed [55, 38]. Incorrect and poor documentation also lead to vulnerabilities. Jia et al. showed how 26 out of the 38 “best practices” in the Amazon Web Services (AWS) [39], the leading IoT cloud platform, official developer guide introduced vulnerabilities.

Albeit security is a primary concern for developers [24, 94], the vast amount of communication protocols and the heterogeneity of IoT environments make it difficult for them to fully comprehend the overall situation. The many protocol standards and the plethora of IoT devices, from pacemakers to smart refrigerators, further complicate the situation. Each device and deployment has different requirements and resource constraints, making developing and enforcing security and privacy measures challenging.

Previous studies focused on identifying device-based vulnerabilities or proposed protocol-specific solutions. Some approaches leveraged companion apps to improve scalability, but mainly focused on device security [78, 90, 14]. There is a need for comprehensive studies assessing the security of IoT backends as they represent an easy entry point for attackers and allow the escalation of attacks to any devices connecting to them [102]. Backends are the backbone of the IoT ecosystem and ensuring their security is critical [2].

In this paper, we fill this gap by measuring the security posture of publicly accessible IoT backends, that is, servers speaking IoT-focused protocols, at scale. We investigate three application-layer messaging protocols widely adopted in the IoT: MQTT, Constrained Application Protocol (CoAP), and Extensible Messaging and Presence Protocol (XMPP).

Maggi et al. [50] and Palmieri et al. [72] provided first insights into the security of MQTT and CoAP backends already, identifying exposure of sensitive information in both cases, for example, ambulances leaking their geographical locations. Our work complements and substantially expands on their work by scrutinizing more and different classes of vulnerabilities, such as DoS, and characterizing security posture of real-world IoT backend deployments at scale.

We do not investigate HTTP backends because determining if it is used in the context of the IoT is extremely challenging. To truly understand if a HTTP backend is involved in the IoT requires a semantic understanding of the exposed API, demanding analyses that do not scale and that would require invasive and ethically questionable probing. These analyses would have to be performed over large parts of the Internet due to the popularity of HTTP, when only a small to negligible number of HTTP backends are involved in the IoT. Generally, HTTP has shifted from being an application-layer protocol to becoming a common transport protocol, for many kinds of applications (e.g., web, DNS-over-HTTPS, etc.). Moreover, we focus on protocols that devices themselves “speak,” while HTTP is mostly used by companion apps [90].

We leverage Shodan to crawl for public backends. We use crawled backends because existing IoT datasets contain an insufficient number of IoT backends, preventing us from painting a complete picture of the ecosystem. From prior datasets, we can only gather 223 backends speaking the selected IoT protocols, while we collect and analyze over 337,000 backends. We infer the backends’ deployed software versions, list their exposed topics and resources, and test if security and privacy measures are in place (e.g., authentication or Transport Layer Security (TLS)). We discover thousands of vulnerable backends and cases of sensitive data exposure. We repeat our evaluation over time to provide a longitudinal view on the security and privacy of IoT backends.

Overall, we make the following contributions:

- We gather a dataset of 337,464 backends speaking MQTT, CoAP, or XMPP, and record 10.6GB of traffic from our interactions, which we make available for future research.
- We characterize the backends in various dimensions, like geographical location and affiliation with cloud providers, to understand their distribution.
- We evaluate backends’ security and privacy posture at scale, studying especially misconfigurations and vulnerabilities. We discover critical security issues, like weak authentication and severe amplification attacks that can enable DDoS.
- We investigate TLS adoption, analyzing their use of insecure versions and cryptography, and expired certificates.
- We report our findings through a Coordinated Vulnerability Disclosure (CVD) process to the backends operators and provide guidance to support their remediation efforts.
- We repeat our analysis over time and show that, despite improvements and our disclosure, some backends exhibit worse security and are affected by more vulnerabilities.

**Ethics Considerations.** Naturally, our large-scale measurement prompts ethics questions. We describe our precautions to prevent potential harms in Appendix A. The Ethics Review Board (ERB) of the University of Twente has reviewed and approved our study. We have also started a CVD process with our national CERT and Cyber Security Center, which we discuss in Appendix B.

**Artifacts.** Our artifacts are available at <https://anonymous.4open.science/r/IoTBackends>. We make our datasets available to other researchers on request, due to the sensitive nature of the data.

## 2 BACKGROUND & MOTIVATION

IoT messaging protocols offer tailored functionalities that account for the characteristics of the devices, their resources, and network constraints. This makes them particularly interesting from a security perspective, as these trade-offs impact confidentiality, integrity, and availability. Following, we introduce the most widely adopted IoT protocols. We exclude HTTP from our study because discerning whether an HTTP backend serves (only) IoT content does not scale and requires invasive and ethically questionable analyses, while HTTP is also mostly spoken by companion apps and mostly used as a transportation vector for additional protocols on top of it [90].

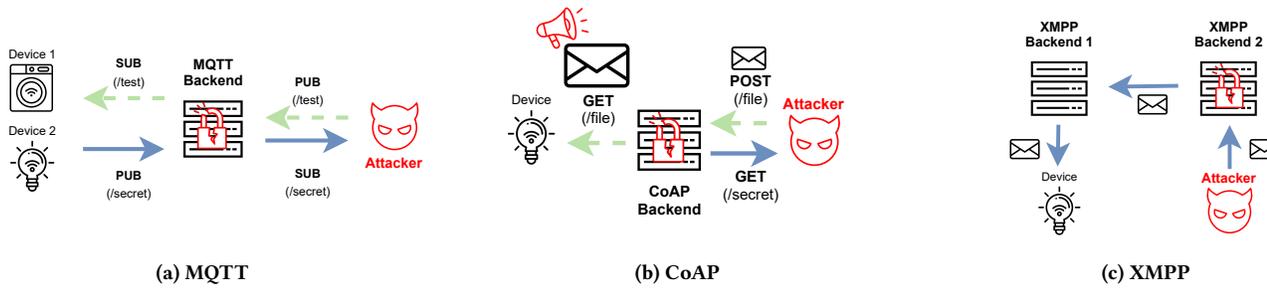

**Message Queue Telemetry Transport (MQTT).** MQTT is a lightweight publish/subscribe IoT messaging protocol standardized by OASIS [10, 9]. Its operation revolves around three entities: the broker, that is, the *backend*, and one or more publisher and subscriber clients, for example, IoT devices. The broker is a centralized entity that receives PUBLISH messages. It routes them based on subscriptions, access control rules, and a Quality of Service (QoS) that can be both associated with the sender or the receivers (i.e., 0 = at most once, 1 = at least once, 2 = exactly once). Publishers typically open a connection with the broker via a CONNECT packet and send one or more messages on specific topics by indicating a QoS. Topics are hierarchically organized paths and can include wildcards (“+” and “#” respectively). Subscribers subscribe to one or more topics via SUBSCRIBE packets.

**Constrained Application Protocol (CoAP).** CoAP is a REST-oriented IoT messaging protocol focusing on resource-constrained Machine-2-Machine (M2M) communication [11]. A client requests a resource from a server, that is, a *backend*, via its URI (Uniform Resource Identifier). The request can be a confirmable (CON) or non-confirmable message (NON). The protocol is asynchronous and relies on UDP (User Datagram Protocol) as the transport, which is connection-less and does not provide a re-transmission mechanism. CON packets guarantee a certain reliability. CoAP methods mirror HTTP methods: GET to fetch a resource, POST, PUT, and DELETE to create, update and delete it. CoAP can be used with Datagram TLS (DTLS) to improve security, known as *coaps*, and it supports four security modes: No Security, Pre-Shared Key, Raw Public Key, and Certificates. Their choice is dictated by resource availability, security requirements, and deployment (e.g., Internet access).

**Extensible Messaging and Presence Protocol (XMPP).** XMPP is an application profile of the Extensible Markup Language (XML). It enables the near-real-time exchange of structured and extensible data between two or more network entities [85, 83], building on a distributed client/server model to exchange “stanzas” (XML data). XMPP relies on TCP and open XML streams to exchange stanzas. It allows client-to-server and server-to-server communication. In the latter, one server acts as a client with the difference that its addresses are known a priori. We consider XMPP servers as *backends*.

### 2.1 Security Concerns with IoT Protocols

**2.1.1 Threats per Protocol.** We focus on distinct threats for MQTT, CoAP, and XMPP, shown in Figure 1. We consider other attacks, like breaking cryptographic ciphers, out of scope.

**Figure 1: Attack Vectors for the Studied IoT Protocols.** We consider three different architectures: Publish-Subscribe (MQTT), Client-Backend (CoAP), and Distributed Client-Backend (XMPP). The colored arrows signify different flows.

**MQTT.** Authentication represents a problematic issue for MQTT. Enforcing authentication via credentials or certificates is possible, but not required. Authorization-wise, only simple Access Control Lists (ACLs) are supported. Data integrity can be enforced via TLS. By default, authentication is not used, even when brokers support password-based authentication. Attackers can sniff credentials by intercepting CONNECT packets as they are sent in plaintext (no TLS). Successfully connecting to a broker puts confidentiality at risk. Attackers may also be able to subscribe to all topics with wildcards and potentially access sensitive information.

Data integrity is at risk if attackers can intercept messages, replay them, or alter their payloads. They could perform confused deputy attacks by modifying a firmware update message files or references.

**CoAP.** Due to UDP’s nature, CoAP is vulnerable to IP address spoofing attacks. UDP cannot authenticate a communication partner; endpoints cannot verify if a packet truly originated from the claimed source IP address. An attacker can send a request with a spoofed IP address, and the backend, since it might trust the source address, might process the request and respond to the spoofed IP address. The server then acts as a “reflector” [50]. CoAP is susceptible to IP spoofing only when not adopting adequate authentication. For example, DTLS enables verification of communication parties.

CoAP can also enable amplification attacks. As it uses the request/response model, the server responds when receiving a request. However, the response size can be substantially larger than the request. Adversaries can send many small request packets to generate large response packets. In turn, amplification combined with IP address spoofing allows attackers to launch DoS attacks at victims.

**XMPP.** XMPP uses TLS with the STARTTLS extension for session encryption, protecting communication from eavesdropping and tampering and allowing to upgrade existing insecure connections to secure TLS ones. However, a downside of STARTTLS is that it makes XMPP vulnerable to downgrade attacks, enabling Monster-in-the-Middle (MITM) attackers to read and modify XML stanzas [61].

Other issues lie in how encryption is used. A stanza can be sent over multiple XML streams, but there is no guarantee that all streams are encrypted. Therefore, end-to-end encryption is vital to protect the stanza on every “hop,” but the XMPP community does not yet provide a suitable technology [84].

**2.1.2 Summary of Threats.** The consequences of security misconfiguration and vulnerabilities in IoT backends vary. We categorize

the threats reported in Section 2.1 in three attack classes. If an attack belongs to multiple classes, we categorize it as the main class.

**Information Leakage.** IoT backends can unveil different types of information, ranging from software information (e.g., library versions) to exchanged messages. In the worst case, an unsecured MQTT broker can expose health monitors’ (e.g., insulin pumps) data and patients’ Personally Identifiable Information (PII) [50], impacting the confidentiality of data. But attackers can also leverage other types of information to gain further access: They can exploit known vulnerable software versions (e.g., leading to crashes or taking over control) or target physical individuals. This threat class is connected to *Weak Authentication*, as an attacker who bypasses authentication can often access unauthorized data.

**Weak Authentication.** Weak authentication mechanisms are a known problem of the IoT. The resource-constrained nature of IoT devices makes adopting security features costly, and often, developers rely on security-by-obscurity, assuming the non-triviality of reversing devices’ firmware [26]. Even when security best practices are adopted, such as TLS, they are often incorrectly implemented. Paracha et al. showed how most devices they tested use old or insecure protocol versions and cipher suites, and lack certificate validation [73]. Bypassing authentication can also allow attackers to gain full control of a system, allowing them to gain access to (sensitive) data, send crafted messages to clients, or spam fake data.

**Denial of Service (DoS).** The problem of DoS attacks is two-fold: (1) an attacker can target an IoT backend, or (2) the IoT devices. In the former case, a malicious actor can impede communication between clients by taking down the backend. In the latter case, the clients would become unresponsive or crash; thus, it would not be able to perform its task. Considering the potentially critical settings of some IoT deployments, like power plant facilities, such attacks could lead to power blackouts in a geographical area. Moreover, backends can act as amplifying reflectors for DoS attacks when their response is larger than the request size. Given the limited resources of IoT devices, even a moderate amplification factor can overwhelm devices. If the victim device is medical (e.g., an insulin pump), then a DoS can cause its users serious life-threatening harm.

## 2.2 Motivating Examples

We discuss two motivating examples that highlight the importance of our study to assess the (in)security of IoT backends. We show

how weak authentication and information leakage can pose serious threats to users’ security and privacy, as introduced in Section 2.1.2.

**Methodology.** Existing research used static analysis for IoT devices’ companion apps to spot vulnerabilities in the devices and to extract their backends [58, 41, 40, 39, 56, 90]. We use the artifact of Schmidt et al. [90] to statically some reconstruct network-related information, specifically the backends that IoT companion apps contact. We investigate two example apps with insecure backends based on the associated devices and the data they exchange.

**Heart & Lung Monitor.** The first example is an MQTT broker we reconstructed from a companion app for a wearable smart device that monitors a user’s lung and heart. We connect to the broker and subscribe to the wildcard topics “#” and “\$SYS/\*” with QoS 0 to avoid acknowledging messages intended for other connected clients and listen to messages only passively. We retain only topic names and “\$SYS/\*” payloads and do not record any other information. Please refer to Appendix A for a complete discussion on ethics.

We find that messages reveal PII of users, such as name, age, and gender, in addition to several health indicators, such as heart and breathing rate, and precise geographical location. An attacker listening to incoming messages can not only precisely identify users and their geolocation, but also alter health indicators. Furthermore, from “\$SYS/\*” payloads, we can infer the mosquito library, version 1.4.15, which was released in February 2018. This version suffers from authorization and denial of service vulnerabilities [64, 65, 66].

**Smart Car Dongle.** We reconstructed the second backend from an app associated with a dongle to bring smart car features to regular cars. Its functionalities include real-time geolocation monitoring, engine monitoring for anomalies, and anti-theft alarms. When connecting to the broker, we discovered that messages reveal sensitive information about the cars’ brand and type, location, fuel consumption statistics, and speed. The broker also unveils users’ email addresses and the anti-theft alarm’s status (i.e., On/Off). The anti-theft status combined with cars’ type and precise geolocation makes a perfect list of valuable cars for thieves to target.

**Summary.** We show anonymized example messages for the two apps in Appendix E. In both cases, weak authentication, or rather a lack of authentication, allows arbitrary anonymous users to connect and read messages. The exposed data we identified is clearly sensitive, highlighting the severity of the problem and potential consequences. We first responsibly disclosed the issues to the developers in May 2023. Please refer to Appendix B for more details on the disclosure process. The developers of the health monitor app replied to our second email. They have deprecated the identified backend and they are moving their services to an AWS-managed backend. Currently, the legacy backend remains available for backward compatibility, until the remaining users updated the app. Unfortunately, we have not received any response from the car dongle manufacturer, even after repeated follow-up emails. Due to the ongoing disclosure, we refrain from naming the apps.

### 3 IOT BACKEND DATASETS

The two motivating examples already show how misconfigured and vulnerable backends can impact users of IoT devices. There is a clear need for a comprehensive analysis of publicly accessible

**Table 1: Datasets Used in Our Study.** We report the number of unique IoT devices used to capture the network traffic, the number of unique backends (based on IP or domain), and the number and percentage of IoT-specific backends (MQTT, CoAP, XMPP). We collected the dataset marked with (\*) from Shodan, thus, only the IoT backends are available.

Dataset	Where?	When?	No. IoT Unique backends		
			Devices	All	# IoT (%)
IoT Sentinel [53]	FI	2016	31	101	0 (0.00%)
UNSW [93]	AU	2016	28	9,610	125 (1.30%)
IoTLS [73]	US	2018–2020	40	1,495	68 (4.55%)
YourThings [4]	US	Q1 2018	45	7,172	32 (0.45%)
Mon(IoT)r [80]	US+UK	Q1 2019	81	3,570	17 (0.48%)
IoTFinder [76]	US	09/2019	53	7	0 (0.00%)
PingPong [99]	US	11/2019	19	6,848	25 (0.36%)
HomeSnitch [70]	US	Q1 2020	24	1,436	57 (3.97%)
Edge IIoT [27]	DZ	01/2022	>10	38	0 (0.00%)
SHODAN-22 (*)	-	07/2022	-	-	901,295 (-)

IoT backends at scale, to identify and understand problems of the ecosystem and propose informed and viable solutions.

To collect a comprehensive dataset of real-world backends that speak IoT protocols, we combine datasets from prior work and collect our own. Table 1 provides an overview of our datasets.

**Existing IoT Traffic Datasets.** We collect nine IoT traffic datasets from prior work. We extract IPs, associated ports and DNS information from traffic dumps (pcaps) and map IPs to domains. IP addresses can vary over time, but this is less likely for domain names, which means they can yield more accurate results. When we cannot match IP and domain, we retrieve the (historic) reverse DNS names for the IP via Shodan [92]. We acknowledge that Shodan’s databases may be incomplete, which is a known limitation of it and related approaches. For our analysis, we consider unique backends for which the associated port is a default IoT protocol port, namely 1883 and 8883 for MQTT, 5683 and 5684 for CoAP(s), and 5222, 5269, 5280, and 5298 for XMPP. Overall, the datasets contain only 45 MQTT, 3 CoAP, and 175 XMPP unique backends. The datasets contain little network traffic for the three IoT protocols, highlighting their partial and limited coverage of the IoT ecosystem.

*Note:* We tried to include the dataset by Saidi et al. [82], but they were not able to share it with us because it contains proprietary data from Farsight. This makes it impossible for us to reproduce or validate their work, or extend it.

**Shodan Crawl (SHODAN-22).** Given the limited coverage of the IoT backend ecosystem of previous datasets, which do not allow a large-scale analysis of backends, we crawl Shodan [92] for Internet-connected devices. We search Shodan in the last week of July 2022 for the keywords *mqtt*, *coap(s)*, and *xmpp*, and find 425,571 MQTT, 474,878 CoAP, 4 CoAPs, and 702 XMPP results, without restricting us to standard ports. We store IPs, available hostnames, and ports and add extra information, such as connection codes.

### 3.1 Dataset Augmentation

After we collected our backend dataset, we augment it with additional information, namely the geographical location and whether hosting is on widely adopted cloud platforms. We use existing APIs from Shodan and WHOIS services to determine the country of the backend. We analyze backends at a country-level granularity, and, thus, our geolocation is sufficiently accurate, as country misclassifications are rare. We also gathered the IP address ranges for ten major cloud providers that offer managed IoT services: AWS, Google, Cloudflare, Microsoft Azure, Alibaba, Oracle, IBM, DigitalOcean, Yandex, and Salesforce [7, 28, 15, 52, 3, 71, 36, 21, 103, 88]. For each backend, we determined if its IP address belongs to one of the providers. If does not belong to one of them, we classify its provider as *Other*. IP address ranges of cloud providers might change over time, which is why include them in our artifact. Finally, we use the regular expression by Saidi et al. [82] to distinguish between self-hosted and managed AWS backends (i.e., hosted on the AWS cloud vs. managed by AWS as part of its IoT cloud).

**Countries.** Most Shodan IoT backends are located in South Korea, followed by China and the Philippines. Interestingly, breaking this down at the protocol level, most MQTT backends are located in South Korea (276,100, 64.88%), followed by China (46,391, 10.90%) and Japan (18,204, 4.28%). For CoAP, most backends in the Philippines (167,849, 35.35%), followed by Russia (104,639, 22.03%) and China (80,619, 16.98%). We explain geolocation trends based on where most manufacturers and vendors are located. Shadowserver, a project funded by the UK Foreign, Commonwealth and Development Office (FCDO), observed a similar trend for CoAP backends. While they only probe for services exposing the resource *.well-known/core*, they saw the same distribution, with the Philippines, China, and Russia making up nearly 93% [1, 43]. Maggi et al.’s 2018 study [50] shows a different country distribution for MQTT and CoAP backends. They identified numerous backends in the US. One reason could be dynamic changes in IoT backends’ locations over time, aligning with major vendors’ (re)locations or increased white-labeling of IoT devices. Another reason could be that some backends are not IoT, but have merely also adopted IoT protocols (e.g., due to similar resource constraints). Given ethical considerations, precise distinction is not possible, as it would require invasive measurements, making our data an upper bound (Section 6). Moreover, other backends using IoT protocols might suffer from the same issues as IoT backends, which is also interesting to study.

**Providers.** We identified the hosting providers for 31,785 backends, of which 25,146 (79.00%) belong to Amazon Web Services (AWS), 3,381 (10.62%) to Azure, 2,292 (7.20%) to Google, 674 (2.12%) to Oracle, 282 (0.89%) to Alibaba and the remaining ten 10 (0.03%) to Cloudflare. Our trend reflects the market share ranking for cloud providers in 2022, with AWS, Azure, and Google being the top three providers [42]. Particularly interestingly is that AWS hosted almost 80% of backends with 34% market share, while Azure and Google account for 11% and 7% backends at 21% and 11% market share respectively. We did not find any backends that were hosted on DigitalOcean, Yandex, IBM, or Salesforce.

## 4 LARGE-SCALE SECURITY ASSESSMENT

Following, we describe our methodology for our large-scale security measurement and assessment of the identified IoT backends (Section 3). We discuss the vulnerabilities and weaknesses that we study and explain their relevance. We also expand on how we implement our approach for each messaging protocol.

The protocols that we investigate have different architectures and face different threats (Section 2), illustrated in Figure 1, Publish-Subscribe (MQTT), Client-Server (CoAP), and Distributed Client-Server (XMPP). Therefore, they require different measurement approaches and we describe our methodology and results per protocol. We also investigate TLS usage for the TCP-based protocols MQTT and XMPP (Section 4.6). TLS is a widely adopted security measure for TCP-based protocols. Since most CoAP deployments rely on UDP, TLS cannot be used and DTLS is required. However, DTLS analysis remains an open research area and only 4 of 474,882 CoAP backends even support DTLS (0.0008%), which is why we leave it for future work. We discuss our results across protocols in Section 5.

Considering the low number of IoT backends from existing datasets and that most were unreachable as of September 2022 (93% were unreachable; we could only connect to one MQTT, zero CoAP, and 14 XMPP backends), we exclude them from our analysis for clarity and readability. We attempted to include additional backends by extracting them from companion apps utilizing the artifact by Schmidt et al. [90], but we could only identify less than 100 backends in over 4,000 manually verified companion apps. Likely, most IoT devices do not rely on the mobile app for communication but communicate with IoT backends directly, which is intuitive, as otherwise they could stop functioning when the phone becomes unavailable. Therefore, utilizing companion apps is unsuitable to identify the devices’ IoT backends, and the limited scale further hinders our large-scale analysis. Thus, we perform our security analyses on the SHODAN-22 backends.

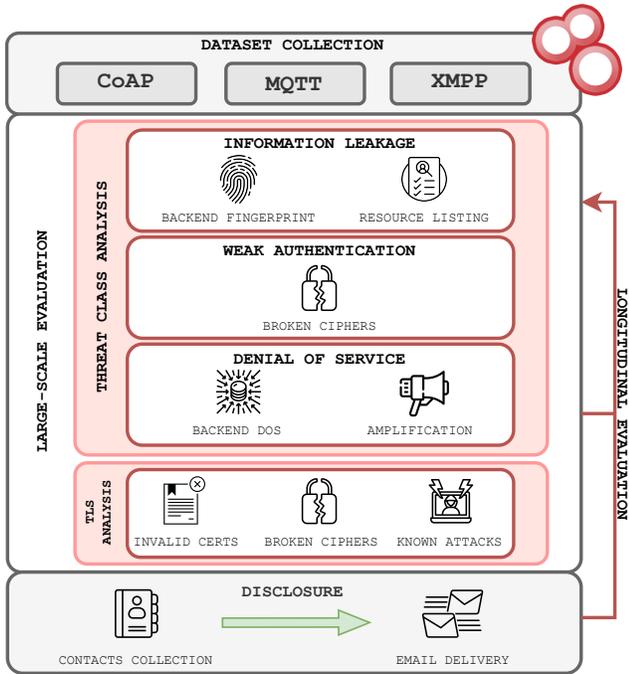

For our analyses, we act as unauthenticated users without any prior knowledge about the target backend. Our measurements do not require privileges (e.g., admin) or authentication. While we can identify vulnerabilities without requiring access privileges, this does not imply that they are always exploitable. We also cannot test for actual exploitability as this would clearly violate ethics and possibly disrupt or compromise services.

Finally, we repeat our analyses after one year to determine if operators improved the security of vulnerable IoT backends over time. We also evaluate the stability of our dataset because IoT traffic datasets tend to age quickly, as seen in Section 3.

### 4.1 General Approach

We identified the main security issues in IoT backends leveraging prior work and following our own classification (Section 2.1.2). Prior work identified insufficient authentication and authorization measures as key issues [57, 2], as well as the adoption of outdated libraries that allow exploitation of known vulnerabilities [50].

We first collect general information for the backends and identify the libraries they use, including their versions. This information can tell us whether a system under analysis adopts the most recent security patches. In this way, we can determine if backends suffer from known vulnerabilities. When available, we also collect

**Figure 2: Methodology Overview.** We first collect our backends’ dataset via Shodan. Then, we perform our large-scale evaluation for the identified threat classes. For TCP-based protocols (i.e., MQTT and XMPP), we also evaluate TLS adoption and implementation. We repeat our analysis over time to understand how security posture evolves, and to consider the impact of our coordinated disclosure.

complementary information, like the authentication mechanisms and the number of connected clients. We then investigate possible information leakage from these backends. First, we analyze the communication structures and determine how messages and resources can be retrieved. We then scrutinize data for privacy issues and confidentiality violations. Considering that we act as an unauthenticated user, we should not have access to any sensitive information and we analyze the information that we can access. Figure 2 illustrates our complete methodology.

## 4.2 Measurement Setup

We perform our initial analyses on 425,571 MQTT, 474,882 CoAP, and 702 XMPP backends between August and November 2022 from the University of Twente, the Netherlands. We perform all tests on an Ubuntu 22.04 virtual machine (VM) with eight CPU cores (Intel Xeon Silver 4110) and 32 GiB memory, with a timeout of 60 seconds per backend. We analyze up to 10 MQTT and CoAP backends in parallel, to minimize network input/output wait times. To foster further analysis, we record all our analysis traffic (10.6 GiB) using tshark, filtered on the backends’ IP, which we make available as an artifact.

**Reproducibility and Tooling.** For some analyses, we adopt and adapt existing security tools. This is motivated by their stability and reliability, and it also makes it easier to reproduce our results. We recommend IoT developers to adopt them for vulnerability testing

of their deployments, making our results more approachable and understandable while fostering scalability. We report the tools and how we utilized them in the approach paragraph for each protocol.

## 4.3 MQTT

**Approach.** We identify MQTT backends and analyze existing topic names using the Paho library (v1.6.1) [47]. We complement the backends we gathered in SHODAN-22 for MQTT with connection codes: If the connection is successfully established, it returns code 0. Otherwise, code 1 to 5 means an error related to connection parameters. We define three cases based on the return code: for code 0, we can connect and proceed; for code 1, we try a different protocol version (e.g., MQTTv5); for code 2 to 4, we mark it as available but requiring authentication or authorization. We connect to them via IP/hostname, port, and protocol version.

After a successful connection, we subscribe to the wildcards “\$SYS/#” and “#” with QoS 0 to avoid acknowledging messages intended for other clients. With QoS 0, messages that we receive are not acknowledged by us and the broker will re-attempt sending them to other (legitimate) clients until they are acknowledged (by them). We listen for incoming messages for 40 seconds. We record the topic names and count the received messages. We do not record message payloads, except for “\$SYS/” topics, which provides relevant information for backend fingerprinting and security analyses, like the broker version or the number of connected clients. While some topic names could include potentially sensitive information, we only record minimal metadata and deem this risk acceptable.

We test for two vulnerabilities via *cotopaxi* (v1.6.0) [89], an IoT pentesting tool by Samsung: CVE-2019-9749 [68] causing the crash of Fluent Bit brokers (version < 1.0.6) and CVE-2018-19417 [63], a stack-based buffer overflow in Contiki OS MQTT brokers (version  $\leq 4.1$ ), by checking the broker version. The former vulnerability makes the broker unavailable via a DoS attack, thus impeding communication between IoT devices. The latter allows remote code execution on the broker and full memory access.

**Results.** Overall, we successfully connected to 251,382 MQTT backends out of the 425,571 (59.07%).

**4.3.1 Weak Authentication.** We observed 12,071 backends (4.80%) that returned a code 4 upon connection, which indicates that they use username-password-based authentication. These credentials are sent in plaintext, which can enable eavesdroppers to intercept them and connect to the MQTT broker, if TLS is not used properly.

**4.3.2 Information Leakage.**

**Demographics.** MQTT allows us to identify the number of unique clients, that is, IoT devices, connected to a broker. Brokers with more clients could unveil more information as more messages might be exchanged, and they can be more impactful targets for DoS attacks. Overall, the average number of connected clients is 11.7 ( $\sigma=538.04$ ), peaking at 33,134 for a single broker. Per geographical region and provider, see Appendix C, the average number of connected clients is less than ten, but with long and dense outlier tails.

**Software.** We identify, when possible, the library and its version adopted by the MQTT broker via messages sent on the topic `$SYS/broker/version`. If this topic is restricted or we cannot connect to the backend, then we cannot infer the software version.

We analyzed version information for 22,986 backends. After removing artifacts, almost all brokers (22,978, 9.14%) use *mosquitto*, which is an open-source MQTT broker by Eclipse [48]. Worryingly, 10,627 backends (4.23%) adopt a library version that was released more than five years ago (version < 1.5). Outdated library versions can be indicative of poor security practices and allow exploitation of vulnerabilities that were addressed in later versions. Updating software versions is, however, not always possible, as some devices might not allow updates. Investigating the vulnerabilities that old *mosquitto* versions suffer from, we find that versions 1.0 to 1.4.15 (10,627 backends, 4.23%) are vulnerable to a null pointer dereference that can cause a broker crash (DoS) [64]. 11,804 backends (4.70%) use versions older than 1.5.5, which exposes them to two authentication and authorization-related vulnerabilities: Malformed data contained in a password file [66] or an empty ACL file [65], which allow attackers to circumvent security checks and access all the information exchanged through the broker.

**Topics.** We perform an in-depth analysis of the topic names we observed to understand what type of data is exchanged. For example, to determine whether it is IoT device data or unrelated. We observed a total of 1,766,804 unique topics (average 39.45 per backend, peak of 36,254 unique topics for one backend) of which 50,167 are *\$\$SYS*/topics. We use the zero-shot classification model by Laurer et al. [45] to analyze if the remaining 1,717,765 topic names fall into nine major IoT-related categories: *health*, *home*, *security*, *update*, *sensor*, *location*, *industry*, *transportation* and *identifier*. For each topic name and category, the classifier assigns a score from 0 (no match) to 1 (perfect match). We require a minimum a score of 0.85, as recommended by Laurer et al., for a topic to match a category. Topics may match zero categories (no score  $\geq$  0.85) or multiple (2 or more scores  $\geq$  0.85). If a topic matches multiple categories, we count it only for the top scoring one. Overall, we classify 697,818 topics (40.62%) into the nine IoT-related categories, providing strong evidence that the brokers are indeed used for IoT communication: 198,031 belong to *update*, 190,312 to *sensor*, 125,723 to *identifier*, 56,080 to *home*, 44,017 to *security*, 30,325 to *industry*, 20,684 to *transportation*, 18,606 to *location*, and 14,040 to *health*.

Manually analyzing the categorized results, we identified topics that might contain sensitive information and which should not be publicly accessible. Following, we redact some of the information to avoid identifiability. For example, *cmd/-/mqttpassword* appears to unveil the MQTT password, while *Security/GarageDoorFront* and *-/Living\_Room/Front\_Door\_Sensor/-/Home\_Security/Cover\_status* appear to allow controlling smart home devices. Several other topics are potentially associated with a firmware update functionality. Delivering an update over plaintext channels is a major security concern for smart devices. If the update is not cryptographically signed, an attacker can replace it with custom malicious firmware [37].

**Case Studies.** We investigate two specific backends in more depth, (1) the backend for which we collected the most topics and (2) the broker with most connected clients.

Analyzing the former’s topics, it appears to correspond to a power plant in China: Two of its topics are *signal-values/admin/-/\_station\_efficient/power-facility-value* and *-/station\_management/alarmSeverityMap*. Exposing such sensitive information is a clear

and severe security threat that could have disastrous consequences, considering how critical the power grid to modern society is.

For the backend with most connected clients, we could not collect any topics. However, it relies on an outdated version of the *mosquitto* MQTT backend, v1.4.14 from July 2017, which suffers from two authentication and authorization vulnerabilities (Section 4.3). Therefore, attackers might be able to exchange messages with a large number of IoT devices (33,134) by exploiting the vulnerabilities and circumventing authorization, while they would otherwise be protected from remote access. This exposes the devices to multiple risks. For example, an attacker could send carefully crafted messages to devices and exploit other vulnerabilities to make them join a botnet, or eavesdrop on their communication.

**4.3.3 Denial of Service.** Finally, we investigate if backends suffer from two known vulnerabilities that can be used to launch DoS attacks, namely CVE-2019-9749 and CVE-2018-19417. We identified 214 and 196 backends affected by CVE-2019-9749 and CVE-2018-19417 respectively. CVE-2018-19417 allows remote code execution, including letting attackers take the broker offline or disconnecting clients, while CVE-2019-9749 crashes the broker directly.

**Recommendations.** We encourage developers to update their broker libraries, thus fixing known vulnerabilities in older versions. We found vulnerabilities affecting broker versions older than five years, signaling bad security practice and not performing updates. We acknowledge that, in some cases, updating might not be trivial, for example, in the case that IoT devices are running old and broken software versions that are incompatible with updates. We suggest stakeholders carefully evaluate what information needs to be accessed and by whom. Adopting authentication measures and ACLs will give developers more control over the data, while also fostering security and privacy. With *Mosquitto*, the most widely used MQTT broker library we found in our results, this can be done straightforwardly with a text file that lists the permission each user has for specific topics. Encrypted communication channels (e.g., TLS) should also be used when possible. Finally, if the broker does not have to be accessible to the entire Internet, access should be restricted via a firewall.

## 4.4 CoAP

**Approach.** We fingerprint backends by collecting the library and the number of connected clients with *cotopaxi*. We compile a list of 30 resources we check for (Appendix D). For example, a CoAP backend exposing the password resource without further protection measures might indicate a sensitive information leak. We include *.well-known/core*, a default URI used as an entry-point for listing the resources hosted by a backend (but not always available). We perform a HEAD request for each resource with a sleep of 1 second and look at the return code. We mark the resource as available if we receive return codes 2.05 (Content) or 2.03 (Valid).

We test for two traffic amplification vulnerabilities with *cotopaxi*, CVE-2019-9750 [69] targeting IoTivity (an open-source framework

for device-to-device connectivity) and ZYXEL\_000 affecting Zyxel Keenetic routers. For both, we send a message and check the response size. If the amplification factor is greater than 100%, we flag the backend as vulnerable. Such vulnerabilities allow attackers to abuse CoAP backends as reflectors to take down connected IoT devices. We also test for the DoS vulnerability CVE-2018-12679 [67]. In this case, the target of the DoS attack is the backend itself, which can no longer serve content to its clients.

**Results.** We successfully connected to 85,957 (18.10%) CoAP backends, which we consider the baseline.

#### 4.4.1 Information Leakage.

**Software.** We identify the software for 2,864 backends: 1,886 (2.19%) adopt *coap-rs* [17], followed by 932 (1.08%) *FreeCoAP* [18], and 19 *aiocoap* [5] instances.

**Exposed Resources.** All 30 resources we defined are available. The resource available across most backends is `.well-known/core` (767 backends, 0.89%), followed by `test` (10 backends) and `help` (6 backends). The resource `admin` is publicly accessible for six backends and `password` for seven. Exposing potentially sensitive content without further security measures is a severe security threat. In four cases, the resource config returned a code 4.01 (Unauthorized), meaning that some authorization measure is in place. Overall, we observed 841 2.05 (Content), four 4.01, 105,673 4.04 (Not Found), and 24 4.05 (Method Not Allowed) return codes.

One backend is exposing all its sensors, actuators, and values/states via a GET request to `.well-known/core`. To not negatively impact the backend, we do not further study these exposed resources and cannot provide more detail. However, motivated attackers do not restrain themselves and can misuse the exposed resources to gather intelligence and possibly perform remote actions. For example, for a smart building, this setting could allow for understanding if it is occupied via its sensors and opening doors via its actuators.

**4.4.2 Denial of Service.** We find 25,928 CoAP backends vulnerable to ZYXEL\_000 (30.16%) and 25 vulnerable to CVE-2019-9750 that can be abused to launch amplification attacks. We record the Amplification Factor (AF) for all backends, that is, how much larger the response size is compared to the request. For our , we only consider AFs  $\geq 100\%$ . For ZYXEL\_000, we find a maximum AF of 849.06% with an average of 240.61% ( $\sigma=25.80$ ). For CVE-2019-9750, we find the same maximum value but a higher average of 517.43%, at a larger standard deviation ( $\sigma=360.07$ ), signifying that there is a difference in AF across vulnerable backends. The AF for ZYXEL is mainly between 200% and 400%, while the distribution is more sparse for CVE-2019-9750. AFs for other protocols, like the Network Time Protocol (NTP), can be higher, up to 200 times the request size. However, CoAP is a protocol for resource-constrained environment, in which even a lower factor can cause DoS. Finally, we found 212 backends (0.25%) vulnerable to CVE-2018-12679. If exploited, such vulnerabilities could cause the collapse of the entire backend by a DoS, thus making all operations and resources unavailable.

**Recommendations.** We suggest developers adopt ACL to limit access to resources on a CoAP backend following the principle of least privilege, that is, a user should only have access to the resources they actually need to operate correctly. Further, we deem it important to prevent access to the `.well-known/core` resource, as this would reveal the structure of the backend. When possible (e.g., if connected clients support it), communication should be encrypted. This can be achieved by adopting DTLS. We also encourage to update and apply patches for old vulnerable library versions, as those allow attacks, such as DoS.

## 4.5 XMPP

**Approach.** We use *nmap* (v7.80) to gather information about the XMPP backends, including their name, version, authentication mechanisms (e.g., PLAIN, DIGEST-MD5), and TLS support [44]. We also employ the *XMPP Compliance Tester* [30] to try registering the account user and to test the backend for a set of compliance requirements, like TLS encryption ciphers etc. [101].

**Results.** We connected to 125 XMPP backends (17.81%) successfully, which is our baseline, while 136 backends were unresponsive (filtered/closed port exceptions).

**4.5.1 Weak Authentication.** PLAIN is the most common authentication mechanism (56 backends, 44.80%). According to the AUTH PLAIN specifications, username and password are sent from the client to the backend as a base64 encoded string. Sending credentials in this way, that is, without encryption, is a security threat. Malicious actors passively listening to the communication can decode the credentials and use them to log in. PLAIN being the top authentication mechanism shows a widespread insecurity of XMPP backends. We also discover DIGEST-MD5 (36 backends, 28.80%) and CRAM-MD5 (33 backends, 26.40%) as authentication methods. Both methods adopt a client-server challenge-response authentication mechanism. In their response, credentials are hashed using the password as the secret key. Generally, DIGEST-MD5 is more secure than CRAM-MD5 as it prevents chosen plaintext attacks [35]. However, considering current computational capabilities, MD5 collisions are becoming achievable, rendering MD5-based authentication methods obsolete and insecure. Finally, we find nine backends (7.20%) with ANONYMOUS authentication, that is, allowing unauthenticated users to access the backend's content.

With *XMPP Compliance Tester*, we can register a dummy user (with username `user`) with no authentication for four backends (3.20%). Registering a user without requesting a password indicates an insecure implementation of XMPP backends. In turn, a malicious actor can send and receive messages without proper authorization, undermining the system's confidentiality and integrity.

#### 4.5.2 Information Leakage.

**Demographics.** The main languages of XMPP backends are Russian for 68 (54.40%) backends and English for 30 (24.00%) backends, providing some insight into their geographical distribution.

**Advertised Features.** Among other features, TLS occurs most often (64 backends, 51.20%). Following TLS are *Roster Versioning*

(29 backends, 23.20%) [87] and *In-Band Registration* (24 backends, 19.20%) [86]. Rosters are users’ contact lists on the backend. *Roster Versioning* saves bandwidth by not sending unmodified rosters.

**Recommendations.** We encourage developers to drop support for weak and broken authentication mechanisms, like PLAIN, as they undermine the integrity and confidentiality of their XMPP backend, potentially allowing attackers to impersonate legitimate users or register new accounts. Moreover, we recommend operators to prohibit user registration without a password.

## 4.6 TLS Analysis

The IoT ecosystem is highly heterogeneous in systems, devices, and underlying topologies. No standard security solution exists that can be readily applied to all of them. Each scenario requires careful adaptation. Nevertheless, TLS provides a fundamental security building block that is widely adopted and supported [73, 12]. Unfortunately, TLS adoption in the IoT domain has been limited because of power/energy concerns [57]. Paracha et al. [73] also found that many IoT devices have wrong TLS configurations, turning them vulnerable to a series of attacks. Following, we scrutinize the corresponding backends. We analyze TLS adoption across our TCP-based protocols, MQTT and XMPP. We leverage *testssl* (v3.1dev) [100] to analyze TLS support and whether cryptographic flaws exist. We extract the supported protocol versions and test for 17 vulnerabilities (e.g., Logjam [60], BEAST [59], SWEET-32 [62]). Additionally, we check whether the certificate has expired or if it was revoked (i.e., if it is in Certificate Authorities (CAs) Certificate Revocation Lists (CRLs)).

We test all XMPP backends and sample a random subset of 100,000 MQTT backends (around 25%), which nevertheless provides statistically significant insight. We automate and parallelize our analysis, using a first timeout of two minutes per backend. We perform our analysis between December 2022 and January 2023.

We successfully connected to 54,503 MQTT and 497 XMPP backends via TLS. Dahlmanns et al. also observed a low TLS adoption rate in their analysis (around 6%) [19]. Interestingly, we find a worryingly low fraction of MQTT backends adopting TLS (0.13%) in our datasets (Table 2), especially considering how critical some of the exchanged messages are. Still far from Dahlmanns et al. results, 2.61% of XMPP backends adopt TLS.

**Protocol Versions and Supported Ciphers.** We find a great share of backends adopting outdated protocol versions, with only 54.65% supporting the latest standard (i.e., only 47 backends support TLS v1.3). Among the TLS-enabled backends, we find that 68.60% support TLS v1 and 70.93% TLS v1.1, both versions were deprecated by the IETF in June 2018 based on the severity of discovered cryptographic attacks. Correspondingly, we test whether backends exhibit weaknesses that could be used to mount attacks. We find that 57 backends (66.28%) are vulnerable to BEAST, which affects TLS versions  $\leq 1$  and allows attackers to capture and decrypt sessions, rendering encryption useless. Additionally, 40 backends (46.51%) are vulnerable to SWEET-32, a weakness in block ciphers discovered in 2016. Although the vulnerabilities are potentially exploitable, some pre-conditions must be met. For SWEET-32, the exploitability

**Table 2: TLS-enabled Backends and TLS Vulnerabilities.** We report the number of TLS-enabled backends together with the adopted protocol versions (from oldest to most recent) and their vulnerability to attacks.

		MQTT	XMPP	Total
<b>TLS support</b>	Number	73	13	86
	Fraction	0.13%	2.62%	0.16%
<b>TLS version</b>	Version 1	52	7	59
	Version 1.1	54	7	61
	Version 1.2	73	13	86
	Version 1.3	42	5	47
<b>Vulnerabilities</b>	BEAST	50	7	57
	SWEET-32	37	3	40
	Logjam	12	3	15

**Table 3: Supported Ciphers by Protocol Version.** Top three most adopted cipher suites by TLS backends for the analyzed TLS versions. We mark the protocols not recommended by IANA (✘).

	Cipher Suite	No.
<b>v1</b>	TLS_RSA_WITH_AES_256_CBC_SHA	✘ 58
	TLS_ECDHE_RSA_WITH_AES_128_CBC_SHA	✘ 58
	TLS_RSA_WITH_AES_128_CBC_SHA	✘ 58
<b>v1.1</b>	TLS_RSA_WITH_AES_256_CBC_SHA	✘ 60
	TLS_RSA_WITH_AES_128_CBC_SHA	✘ 60
	TLS_ECDHE_RSA_WITH_AES_256_CBC_SHA	✘ 59
<b>v1.2</b>	TLS_ECDHE_RSA_WITH_AES_256_GCM_SHA384	83
	TLS_RSA_WITH_AES_128_GCM_SHA256	✘ 83
	TLS_ECDHE_RSA_WITH_AES_128_GCM_SHA256	73
<b>v1.3</b>	TLS_AES_256_GCM_SHA384	47
	TLS_AES_128_GCM_SHA256	47
	TLS_CHACHA20_POLY1305_SHA256	45

depends on whether the affected ciphers are indeed chosen (proposed by the client, picked by the server), and it generally requires a large number of payloads, the threshold of which may or may not be realistic for an IoT device (depending on connection lengths etc.). Finally, we find 15 backends (17.44%) potentially vulnerable to Logjam, a flaw affecting systems adopting the Diffie-Hellman key exchange with the same prime number, first discovered in 2015. Since then, a 2048-bit shared prime number is considered required.

We additionally analyze the cipher suites that the TLS-enabled backends support and report the three most common ones per TLS version (Table 3). Most of them are not recommended by the Internet Assigned Numbers Authority (IANA), that is, they have not been through the consensus process or have limited scope. Some backends also adopt known weak (broken) cryptographic protocols and hash functions. Specifically, two backends adopt RC4 (2.33%), 40 adopt 3DES (46.51%), 75 adopt SHA-1 (87.21%), and two adopt MD5 (2.33%). These algorithms and hash functions have (long) been deprecated because they are vulnerable to attacks.

**Certificates.** We find two expired certificates. On average, certificates have an expiration date of ~200 days with one extreme outlier

of 982 years. When available, we also retrieved the CRLs from the CA for each backend’s certificate and determined if the backend’s certificate was revoked. We found no revoked certificate.

Additionally, we analyzed whether the host name and Common Name (CN) or Subject Alternative Names (SANs) contained in the certificates match. We find 26 of 85 certificates mismatch (30.59%). This suggests that IoT devices do not properly validate TLS certificates, rendering them susceptible to MITM attacks, or that they use certificate pinning with its associated problems. This is important as devices might contain old certificates that are replaced on the backend while the devices cannot reach the backend. This mismatch “bricks” the devices or exposes them to security issues: Devices cannot recognize valid backends anymore and they cannot download new certificates or security patches [37].

#### 4.7 Longitudinal Analysis

Next, we provide details how backends change over time in their security posture. Following, we contextualize the evolution.

**IoT Protocols Analysis.** We first repeat our security assessment between September 15th–30th, 2023. We study 29,077 MQTT, 28,974 CoAP, and 124 XMPP vulnerable backends. Overall, 13,257 MQTT (45.59%), 13,573 CoAP (46.85%), and 35 XMPP (28.23%) backends are now unresponsive or offline. As we discussed (Section 3), IP addresses can be volatile, and backends may no longer be reachable at the same address. We also faced this issue when analyzing others’ datasets (Section 3). We overcome this shortcoming by scrutinizing the domains we collected and analyzing the backends’ new IP addresses, focusing on 17,742 MQTT, 14,288 CoAP, and 48 XMPP vulnerable backends. In some cases, Shodan does not report any associated domain with the IPs, leading to fewer domains.

Among the responsive backends, some no longer exhibit any security vulnerability, indicating that security issues were addressed. We find that 314 MQTT (1.08%), 149 CoAP (0.57%), and six XMPP (6.06%) backends are no longer vulnerable as of September 2023. Unfortunately, other backends have worse security. While 14 CoAP backends (-6.60%) are no longer vulnerable to CVE-2018-12679, 23 new backends (+10.85%) are now vulnerable. Similarly, 147 more MQTT backends (+35.85%) turned vulnerable to DoS threats, while only 84 backends (-20.49%) addressed the vulnerabilities. On a positive note, 185 CoAP backends (-23.75%) exposed fewer resources than in our previous analysis (16, +2.05%, exposed more resources). Finally, 262 MQTT backends (-2.17%) suffer from fewer CVEs from adopting older library versions. This is reflected in the number of backends that use newer updated library versions: 527 MQTT backends use newer software. Interestingly, we also discovered 40 backends that went backward to an older and vulnerable version.

We repeat our analysis a second time between January 23rd–31st, 2024, after we sent our disclosure emails, to understand whether developers who had been made aware of the vulnerabilities addressed them. Overall, we encounter a similar instability as in our second scan and find 15,909 MQTT (54.71%, +12.12%), 15,203 CoAP (52.47%, +5.62%), and 38 XMPP (30.65%, +2.42%) backends unresponsive or offline, showing how, over time, datasets age quickly, resulting in 13,168 MQTT, 13,771 CoAP, and 86 XMPP responsive backends.

We find that, in addition to the backends that fixed their vulnerabilities in 2023, 74 MQTT (0.56%) and 72 CoAP (0.52%) backends no

longer suffer from vulnerabilities. Similar to 2023, we find that 145 MQTT (+30.66%) backends became more vulnerable to DoS attacks, while only 127 (-26.85%) addressed the issue. For the remaining vulnerabilities, we observe slight improvements.

**TLS Analysis.** We repeat our TLS analysis between October 15th–30th, 2023. Given reachability instability for IP-based backends, we successfully analyzed 38,034 MQTT and 48 XMPP backends, of which only 25 MQTT (0.07%) and 3 XMPP (7.89%) backends support TLS. Interestingly, the two backends that served expired certificates in the past provide the same old certificates, signaling poor security practices. We find 4 MQTT backends that show worse security in their TLS configuration. One now supports the outdated SSLv3 version, making it vulnerable to more attacks (e.g., SWEET-32).

## 5 DISCUSSION

Following our study of the individual protocols and TLS, we discuss characteristics and statistics of our results, contextualize findings, and provide detail on trends.

**Results per Threat Class.** We summarize the analysis results according to our categorization in Table 4. Considering the number of vulnerable backends per category, we see that a large fraction of reachable MQTT (11.47%) and XMPP (72.95%) backends are vulnerable to information leakage threats, with topic enumeration being a superset of backend fingerprinting for MQTT. For all reachable MQTT backends for which we collected topic names, we obtained fingerprint information, for example, the software version or the number of clients. CoAP backends are particularly vulnerable to DoS attacks or are even enabling them (30.38%). This may be due to CoAP being UDP-based. Noteworthy is the large amount of CoAP backends that act as amplifying reflectors (30.18%), posing a severe risk to the Internet.

**Results per Geographical Location.** Concerning MQTT topic enumeration by country, most information leakage occurs for backends located in China (729,425), followed by the US (422,771) and Germany (247,663). Except for China, this trend does not reflect the geographical distribution of brokers we observed in Section 3.1. On average, these countries reveal more topics per backend than the countries with most MQTT brokers.

We observe that 24,519 CoAP backends vulnerable to ZYXEL (94.57%) are located in Russia, and they represent the vast majority of Russian CoAP backends (99.68%). The vulnerability ZYXEL affects various Keenetic routers and enables DDoS attacks, potentially rendering thousands of devices unavailable. One reason for this localization in Russia could be an ISP providing vulnerable routers to its customers. Albeit Russian CoAP backends account for the majority of DoS amplifiers and reflectors, they expose fewer resources, with only 0.21% backends exposing any resources. Somewhat counterintuitively, backends in Europe and the US exhibited more information leakage in 2022, with 30.98% and 39.62% backends, respectively, exposing resources. This is despite stricter privacy regulations, like the European General Data Protection Regulation (GDPR). Interestingly, this improved in 2023, with now only 20.77% European and 27.99% US CoAP backends exposing resources, indicating that improvements to securing were made. One reason might be that, in addition to the GDPR, the California Privacy Rights

**Table 4: Vulnerable Backends per Threat Class.** Overview of the analyses per protocol and threat class. We group the results of our individual analyses by vulnerability to provide a more comprehensive overview. A considerable share of backends in our dataset is vulnerable, potentially affecting the confidentiality, integrity and availability of user data.

Prot.	Threat Class & Analysis	No. Vuln.	Fraction
MQTT	<i>Information Leakage</i>	28,830	11.47%
	Backend Fingerprint	23,120	9.20%
	Topic Enumeration	28,830	11.47%
	<i>Weak Authentication</i>	12,071	4.80%
	DoS	410	0.16%
	Known Vulnerabilities (backend)	410	0.16%
CoAP	<i>Information Leakage</i>	2,928	3.41%
	Backend Fingerprint	2,864	3.33%
	Resource Listing	779	0.91%
	DoS	26,117	30.38%
	Amplification Factor (client)	25,939	30.18%
	Known Vulnerabilities (backend)	212	0.25%
XMPP	<i>Information Leakage</i>	89	72.95%
	Backend Fingerprint	89	72.95%
	<i>Weak Authentication</i>	59	48.36%
	Supported Authentication Mechanism	56	45.90%
	Compliance	4	3.28%

Act (CPRA) [13] came into effect on January 1st, 2023, requiring companies to put more care into handling users’ data.

XMPP backends in the EU are generally more secure than those in the US, China, or Russia: 25.58% EU backends are vulnerable compared to 44.44–56.25% in other countries.

Overall, in 2023, compared to our 2022 results, the percentages of vulnerable backends in the analyzed countries slightly decreased for all vulnerability categories except for DoS threats for MQTT, for which we instead witness a slight increase in vulnerable backends in Europe (21 to 30), the US (18 to 22), and China (259 to 294).

**Results per Cloud Providers.** Taking a look at backends’ deployments, we observe that MQTT backends hosted on larger cloud providers (AWS, Google, Azure, Alibaba) exhibit worse security than those hosted on *Other* (Table 6). While we cannot identify a clear trend for XMPP, it unambiguously reverses for CoAP: Cloud providers generally show better security.

The trend of generally better security is, however, not uniform. Cloud-hosted CoAP backends leak more information than *Other*. In 2022, over one-third (34.76%) of AWS-hosted backends exposes at least one resource, contrary to only 0.68% *Other* backends. This improves substantially in 2023 for cloud-hosted backends: Only 17.63% AWS-hosted backends leak resources and the number of Google-hosted backends that expose resources halves (50.77% to 24.61%), indicating that security is receiving some attention. Fortunately, considering their network capacity, almost no cloud-hosted backends are vulnerable to DoS amplification vulnerabilities (0.75%), while almost one-third of *Other* backends are (30.58%). This number remains stable in 2023, suggesting that these providers adopt the latest security updates to mitigate abuse while other operators do not. At the same time, backend operators are still responsible

for configuring the cloud-hosted backends properly to prevent information leakage, and the complementary disparity we observed provides a unique opportunity for future human factors work.

**Self-hosted AWS vs. Managed AWS.** Matching hostnames in our dataset against regexes of hostnames of services managed by AWS [82], we find only 125 instances that are managed MQTT backends (3.10% of AWS backends). Interestingly, we failed to connect to all 125 backends, possibly because they were unavailable or implement ACLs properly. Indeed, AWS IoT adopts certificates to authenticate clients, which may prevent us from successfully connecting. They might also use Amazon Cognito to obtain (temporary) limited-privilege credentials. However, this does imply that these backends are secure. Companion apps might use credentials to authenticate their connection to the backends and carelessly hardcode the credentials in the app code [41]. Since we do not know if backends are associated with any app, we leave managed AWS backends for future work and consider them “secure.”

Looking at Table 6, we can see that around 71.43% self-hosted AWS backends are vulnerable to some threat class, from information leakage to DoS. Hence, we highlight the risk of inexperienced users misconfiguring AWS instances and potentially exposing sensitive information; this is less likely in the case of instances created directly by AWS, as our results show.

**Ethical Considerations.** Active measurements, like ours, raise ethical concerns that demand proper consideration. For our evaluation, we followed guidelines defined by the Ethics Review Board (ERB) of the University of Twente, which reviewed and approved our study (see Appendix A for an in-depth discussion). When devising our measurement methodology, we put particular care into performing analyses that do not alter state. We do not control the backends and interfering with their operation, such as impeding or disrupting their service, would clearly raise ethical concerns. Therefore, we do NOT perform any actions that could compromise the correct functioning of the backends, such as ones leading to DoS. Further, we only provide aggregated data that cannot be associated with any specific service.

**Responsible Disclosure.** We have also started a Coordinated Vulnerability Disclosure (CVD) process to inform developers and operators about the issues we discovered, which is still ongoing. We report for each backend, the scan date, our methodology, and the vulnerabilities we found. As the disclosure process is auxiliary to our research, we provide more details in Appendix B. So far, we have sent 2,135 emails (for 15,810 IP addresses) and received 765 responses, categorized in Table 5. Naturally, we will continue this process and update our results.

## 6 LIMITATIONS & FUTURE WORK

Our results clearly show a problematic security immaturity in the IoT ecosystem. All analyzed IoT protocols’ backends present some vulnerabilities. Following, we discuss possible threats to the validity of our study and open challenges for future work.

First, we acknowledge that our dataset might intrinsically contain geographical or provider bias. We could not find many backends in prior IoT traffic and were unsuccessful when asking other researchers to share theirs. At the same time, the high number of backends on Shodan shows a problematic lack of coverage of

**Table 5: Count of Responses.** We grouped the responses we received from the disclosure emails we sent into categories.

Type	Count
Listed CVEs do not apply. Provide more information.	23
We have informed the responsible parties.	15
We fixed the issues with your information.	11
We do not have time.	3
We will let you know what we will do.	2
The vulnerable client has been blocked.	1
Automatic Reply	428
Failed Delivery	282

**Table 6: Vulnerable Backends per Provider.** Number of vulnerable backends by provider and protocol together with the respective fraction (computed on the total backends belonging to a specific provider). Considering their low numbers, we merge Cloudflare and Oracle with *Other*.

		AWS	Google	Azure	Alibaba	Other
MQTT	Total	4,036	606	854	131	245,753
	Vulnerable	2,883	409	625	45	25,091
	Fraction	71.43%	67.49%	73.18%	34.35%	10.21%
CoAP	Total	397	65	100	6	85,389
	Vulnerable	3	0	0	0	26,114
	Fraction	0.76%	0.00%	0.00%	0.00%	30.36%
XMPP	Total	7	-	1	-	118
	Vulnerable	5	-	1	-	93
	Fraction	71.43%	-	100.00%	-	78.81%

existing datasets and limited visibility into the ecosystem. Further, our dataset is mostly IP-based, as not all Shodan results include a hostname. As discussed (Section 4.7), relying on IPs can hinder stability. In future, we aim to gather a more heterogeneous dataset.

Second, we were limited in the range of vulnerability analyses we could perform. To preserve the correct functioning of the analyzed services and avoid disruptions or interruptions, we did not perform invasive measurements, for example, testing carefully crafted malformed payloads. Our analysis cannot guarantee complete insights about the security posture of IoT backends, because there might be other potential threats they are exposed to, which we did not investigate. Nevertheless, our results show that, clearly, additional steps need to be taken to improve IoT security.

Further, we cannot rule out that some backends we analyze are not IoT, some might be IoT-related or IoT-adjacent. Performing the necessary experiments to accurately assess whether a backend speaking an IoT-focused protocol is truly IoT would cross ethical and likely legal boundaries. Specifically, if we wanted to investigate the backends further and test if the connected clients are IoT, we would need to perform invasive measurements of the connected clients and instruct them to perform some action that we can use to determine that they are IoT. This is clearly much more ethically challenging, if not downright impossible to do ethically or legally.

We cannot rule out that our dataset contains honeypots. To the best of our knowledge, only one IoT-focused honeypot exists currently [97], which provides only basic functionality and has not been deployed widely. To quantify this issue, we employ Shodan Honeyscore [31], which has been integrated into the regular crawlers since its first release. We find only 36 instances of the MQTT backends for which the “honey\*” keywords have been set, which gives us an indication that they almost certainly represent negligible noise. Unfortunately, we cannot rule out that other backends are honeypots without more invasive measurements.

Finally, we focused on three widely adopted IoT protocols and considered more general protocols, like HTTP, out of scope. Despite HTTP usage in the IoT ecosystem [23], distinguishing IoT HTTP backends from non-IoT ones is extremely challenging, requiring a semantic understanding of its API and manual inspection, which does not scale and requires invasive analyses. We leave their study for future work. Other non-application-layer IoT protocols, like Z-Wave, Zigbee or RFID, have been studied by prior work [2, 104] and are local only, while we analyze public remote backends.

## 7 RELATED WORK

**IoT Protocol Security.** Maggi et al. [50] investigated the security of MQTT and CoAP. They found sensitive healthcare data, such as patients’ PII and ambulance locations, exposed by insecure MQTT brokers. Additionally, they found 365,000 CoAP backends exposing network credentials. Palmieri et al. [72] showed the insecurity of MQTT backends, with 24,361 backends (60.38%) allowing clients to simply connect. They proposed MQTT-SA, a tool to assess MQTT deployments’ security and detect possible misconfigurations. Jia et al. [39] successfully exploited MQTT device sharing or access revocation weaknesses to send unauthorized messages using “Will and Retained.” Andy et al. [6] also investigated the implementation issues of MQTT, such as lack of authentication and encryption. Paracha et al. [73] studied how different IoT devices use TLS by collecting device traffic for two years. Their results show that some devices adopt old or insecure protocol versions or lack certificate validation. However, the studies and methods of prior work do not scale and are not applicable for publicly exposed backends, as they are invasive and potentially cause crashes. Instead, in this paper, we focus on the backend, measuring and characterizing security and privacy in the IoT ecosystem at scale.

**IoT Analysis at Scale.** Saidi et al. [82] studied the geographic location of IoT backend providers. They found that ~35% of IoT traffic at a major European ISP is going to providers located outside of Europe, raising regulatory concerns. Srinivasa et al. [96] perform Internet-wide scans on six protocols, including the protocols we study in this paper. They find over 1.8 million misconfigured IoT devices that can either be infected with bots or be leveraged for a (D)DoS amplification attack. Dahlmans et al. [19] studied TLS adoption of ten Industrial IoT protocols, showing a low deployment rate (6.5%) and other wide-spread security issues (e.g., outdated protocol versions). Other work focused on large-scale identification of IoT devices and related events based on network traffic characteristics and packet signatures [93, 22, 70, 76, 53, 99]. Recent work investigated IoT companion apps at scale [14, 20, 80, 78] looking for security and privacy issues of devices without direct access to

them. Schmidt et al. [90] statically reconstruct network-related data as URLs contacted by 9,889 companion apps and discover various security and privacy issues, such as hard-coded credentials. To the best of our knowledge, prior work did not study IoT backend security, which is a gap we fill in this paper.

## 8 CONCLUSIONS

In this paper, we perform a large-scale measurement of the security posture of over 900,000 IoT backends that use MQTT, CoAP, or XMPP, focusing on three main threats: information leakage, weak authentication, and DoS potential. We find that many deployments for all three protocols are vulnerable: 31,847 of the reachable backends (9.44%) expose (sensitive) information, a conspicuous fraction of CoAP backends (30.18%, 25,939 backends) are vulnerable to amplification attacks, and only a negligible number of MQTT and XMPP backends adopt TLS (0.16%), of which 70.93% use outdated protocol versions ( $< 1.1$ ). Our study provides evidence for a troubling immaturity of security in the IoT ecosystem, which was not analyzed thoroughly at scale before. We responsibly disclosed the identified issues to the affected parties, support their remediation efforts, and hope to improve their security awareness.

## ACKNOWLEDGEMENTS

## A EXTENDED ETHICAL CONSIDERATIONS

In our research, we performed large-scale active measurements, also called scans, of real-world deployments. This prompts important ethical considerations, similarly to prior studies [95, 16, 77]. We followed the guidelines and best practices established in the Menlo report [8] and also discussed in recent work on cybersecurity research and network measurements [49, 75, 74]. Our study has been approved by the Ethics Review Board (ERB) of the University of Twente, which assessed our setup and measurement methodology. We note that, in recognition of a historic lack of computer science expertise in the ethics review process, our ERB operationalizes the inclusion of cybersecurity expertise in its review, including guidance on coordinated vulnerability disclosure. Naturally, we are more than happy to provide more details on the exact composition of our ERB and how it includes cybersecurity expertise on request and in coordination with the PC chairs, we omit this information here to not break anonymity.

### A.1 Active Measurement Setup

We performed our active measurement ethically. First, we limited the number of requests that we perform with our scanners to limit the impact we have on backends. The machine that we used to perform our measurements has a static IP address in the University of Twente’s IP address space and has a clear registered abuse handle. We also set up a reverse DNS entry with a descriptive DNS name for the IP address (<https://iotscan.eemcs.utwente.nl/>) and we host an informative web page on the same machine (reachable directly via IP address and DNS name). These measures aim to quickly and clearly inform the backends’ developers and maintainers about the nature of our measurement (e.g., by directly seeing `iotscan.eemcs.utwente.nl` in their log files and then visiting the website that provides more details), so that they can understand the scope of our study, and can contact us to request even more details or to be excluded from our study. We do not require a reason to be excluded from our measurements. We received no exclusion requests.

Second, we only conducted *non-invasive* tests to not alter the state of the analyzed backends, carefully considering the trade-off between the utility of our study and potential harms. We only detect vulnerabilities and we did *not* attempt to exploit them. This limits the accuracy of our findings, as in some cases the identified vulnerabilities may not actually be exploitable, but it is necessary to not cause harm and to ethically conduct our research. We thoroughly evaluated the trade-offs that could cause unintended harm by our measurements with respect to its benefits, which includes providing valuable knowledge to the scientific community and practitioners to protect users by discovering and reporting critical vulnerabilities, so that they can be addressed. We are convinced that the contribution we make in our work, especially considering the plethora of potential threats that we discovered within the IoT to privacy, self-determination, and even life, considerably outweighs the remaining minimal risks of our measurement.

Third, we did not read or store sensitive data. Albeit data could include sensitive information, such as usernames, we only collect the minimally necessary metadata (i.e., topics and resource names) to perform our assessment. We do not collect any potentially sensitive

content, to mitigate potential unknown risks. Thus, our analysis is a lower bound, as other (and more) sensitive data might also be exposed. We test if resources (e.g., /password) are exposed via HTTP HEAD requests and the response code, that is, an existence check, and we do not request or receive any content.

Finally, we do not disclose the affected backends and put particular care into anonymizing our results and only presenting aggregates. When discussing case studies, we do not provide information that links to the specific backend. We will allow researchers to access our anonymized dataset after verifying their roles and institutions.

## B COORDINATED VULNERABILITY DISCLOSURE

Given the scale of our study and the many vulnerable backends we identified, responsible disclosure is particularly challenging: It involves the operators of tens of thousands of backends. Therefore, we are collaborating with our National CERT and Cyber Security Center, who are supporting our responsible disclosure efforts. We adopt a twofold approach.

First, we started our disclosure process with the two motivating examples in Section 2.2. We emailed the affected parties via the contact information we found on their respective websites in May 2023, following the approach by Reidsma et al. [79]. We sent an informative email stating who we are, the scope of our research, the vulnerabilities we found, how it could affect their backend, and suggestions on how to address it. We then sent follow-up emails in the following weeks, the first after 21 days and the second after 60 days. We only received feedback from one of the two impacted apps at the time of submission.

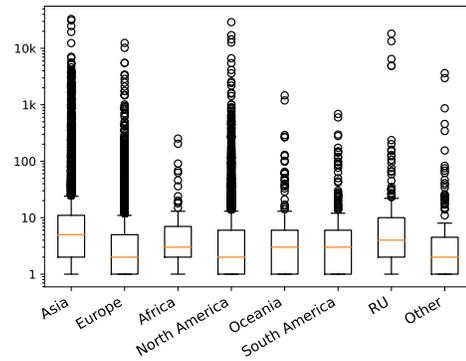

Second, for our large-scale study, we check whether an IP address falls within the IP address ranges of major cloud service providers (e.g., AWS, Google Cloud, etc.), in which case we disclose our findings directly to the providers. For the remaining backends, we utilize WHOIS data to extract their associated email addresses. We extract this information twice, for our first measurement (October 2022) and for our second one (September 2023), in case some addresses have changed. We extracted one or more email addresses for 273,151 MQTT, 290,901 CoAP, and 125 XMPP backends. We started our large-scale responsible disclosures in November 2023, accounting for the need to understand the evolution of security and privacy in the IoT ecosystem undisturbed while minimizing risks. Importantly, we have been working with our national Cyber Security Center since May 20th, 2022, i.e., well before our first measurement, to determine the best and most effective disclosure approach that minimizes overall harm.

We grouped all backends for which we reconstructed the same email address in a single email to reduce the total number, such as those by cloud providers and other large hosting providers. Some maintainers and developers may require more information and suggested solutions, which is why we drafted a file with an in-depth description of the identified vulnerabilities and how they impact their services. Moreover, although we cannot give detailed information on how to address vulnerabilities as we do not have access to their backends, we provide some general guidelines. For example, when vulnerabilities stem from old library versions, we

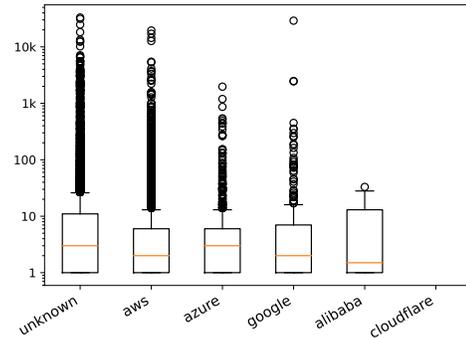

suggest to update to a newer version. Similarly, for information leakage issues, we advise to:

- (1) Adopt authentication measures, e.g., (at least) passwords.
- (2) Adopt ACLs to prevent users from reading (all) messages, e.g., so that only admins can read sensitive topics.
- (3) Encrypt communication, e.g., using (D)TLS.
- (4) If the backend does not have to be exposed to the Internet, protect it behind a firewall (blocking incoming connections from outside the organization).

## C MQTT CONNECTED CLIENTS

**Figure 3: Number of Connected Clients to Individual MQTT Backends Grouped by Continents.** We see how Asia has the most dense tail, indicating that a great share of MQTT backends are located in that geographical area. Conversely, the densities of Africa, Oceania and Russia are lower.

**Figure 4: Number of Connected Clients to Individual MQTT Backends Grouped by Providers.** Alibaba brokers show fewer connection but a trend cannot be inferred because of a low number of representatives.

## D LIST OF COAP RESOURCES

- **Resources:** helloWorld, test, login, admin, administrator, adm, .passwd, passwd, history, certificates, logout, password, log, logs, about, actions, advanced, auth, backup, .well-known/core, .history, certs, config, configuration, data, dev, files, help, resources, items.
